Abstract: We report a phosphine (PH₃) plasma activation strategy for significantly boosting the electrochemical performance of supercapacitor electrodes. Using Fe₂O₃ as a demonstration, we show that the plasma activation simultaneously improves the conductivity, creates atomic-scale vacancies (defects), as well as increases active surface area, and thus leading to a greatly enhanced performance with a high areal capacitance of 340 mF cm⁻² at 1 mA cm⁻², compared to 66 mF cm⁻² of pristine Fe₂O₃. Moreover, the asymmetric supercapacitor devices based on plasma-activated Fe₂O₃ anodes and electrodeposited MnO₂ cathodes can achieve a high stack energy density of 0.42 mWh cm⁻³ at a stack power density of 10.3 mW cm⁻³ along with good stability (88% capacitance retention after 9000 cycles at 10 mA cm⁻²). Our work provides a simple yet effective strategy to greatly enhance the electrochemical performance of Fe₂O₃ anodes and to further promote their application in asymmetric supercapacitors.

Keywords: hematite, Fe₂O₃, plasma activation, supercapacitors, energy storage

1. Introduction

Supercapacitors (SCs), also known as electrochemical capacitors or ultracapacitors, have attracted significant research interest due to their high power density, long cycle lifetime, and fast charge-discharge rate.[1, 2] However, to meet the demands of emerging markets including hybrid electric vehicles and next-generation electronic devices, the energy density of SCs needs to be further improved, without sacrificing their power density. According to the equation $E = \frac{1}{2}CV^2$, where E is the energy density, C the capacitance, and V the operation voltage window,[3, 4] the energy density of SCs can be enhanced by increasing the device capacitance and/or broadening the cell voltage. The latter approach can be achieved by using ionic liquids or organic electrolytes, which normally possess much wider voltage windows (more than 2 V) compared to aqueous electrolytes (limited to 1.23 V due to the water splitting reaction).[5] However, ionic liquids are costly whereas organic electrolytes are generally poor ionic conductors and not environmentally friendly, making both electrolytes not ideal for SCs. Alternatively, fabrication of asymmetric supercapacitors (ASCs) with aqueous electrolytes provides an effective way to improve the energy density.[6] ASCs typically consist of a cathode and an anode that work in different potential windows, leading to a broadened cell voltage and thus a higher energy density compared to symmetric SCs. It is noted that the overall performance of ASCs essentially relies on the properties of electrode materials. Enormous efforts have therefore been devoted to exploring new electrode materials and to optimizing their performance.[7, 8] Compared to the great achievements that have been made on cathode materials, anode materials however, have long been the bottleneck limiting the practical application of ASCs. Carbon materials are commonly used anodes, which possess excellent cycling performance and good power density, but suffer from low energy density resulting from their low capacitances.[9, 10] Alternative electrodes with high capacitance such as Fe_2O_3 , VN, MoO_{3-x} have thus been investigated, aiming to improve the energy density

of ASCs.[11-14]

Among these anode materials, Fe_2O_3 has received growing attention in recent years owing to its earth abundance, high theoretical specific capacitance, and suitable negative potential window.[14-21] Many strategies have been proposed to enhance the performance of Fe_2O_3 anodes, e.g., by delicate nanostructuring to increase the effective surface area,[14] by hybridizing with carbon materials or doping to enhance the electric conductivity,[15, 17, 19] or by defect engineering to improve the reactivity.[21] Unfortunately, despite the great progress that has been achieved, the performance of Fe_2O_3 anodes is still unsatisfactory and further improvement is needed. Combining these strategies might further enhance the performance but has rarely been achieved mainly due to the complexity of putting reaction schemes involved in different synthetic methods together.

In this work, we present an “all-in-one” phosphine (PH_3) plasma activation strategy that could simultaneously tune the active surface area, conductivity, and vacancy (defect) concentration and thus significantly boost the performance of Fe_2O_3 anodes. Plasma has been employed as an effective surface modification technique since 1966,[22] which provides a possibility to selectively modify the surface without changing the bulk properties.[23, 24] The changes of surface highly depend on the gas type and typical gases used are O_2 , H_2 , N_2 , and Ar.[25-29] The N_2 plasma has recently also been used for the synthesis of metal nitrides.[30-34] While these gases are normal, the use of PH_3 plasma is much less common, which has been so far mostly used for passivation of (In)GaAs semiconductors.[35] We previously demonstrated that PH_3 plasma can be used to convert various precursors into phosphides (e.g. NiCoP , NiFeP , Ni_2P) at low temperatures in a short reaction time.[36-39] Such unique plasma conversion is a powerful and versatile tool that should also work for the synthesis of FeP . It should be pointed out, however, that FeP is a good hydrogen evolution reaction (HER) electrocatalyst with a small onset potential,[40] meaning that when it serves as a

supercapacitor electrode, the working potential window would likely narrow as compared to Fe_2O_3 , which is undesirable as the narrow potential would lower the energy and power density. Herein, we suggest that PH_3 plasma could be also used to activate the Fe_2O_3 but without changing the bulk phase. We show that the PH_3 plasma activation effectively tunes the active surface area, electric conductivity, as well as defect concentrations, and thus leading to a greatly enhanced performance. Specifically, the PH_3 plasma activated Fe_2O_3 ($\text{Fe}_2\text{O}_3\text{-P}$) can deliver a high areal capacitance of 340 mF cm^{-2} at 1 mA cm^{-2} in $1 \text{ M Na}_2\text{SO}_4$, compared to 66 mF cm^{-2} of pristine Fe_2O_3 . Encouragingly, the ASCs based on $\text{Fe}_2\text{O}_3\text{-P}$ and MnO_2 achieved a high stack energy density of 0.42 mWh cm^{-3} at a stack power density of 10.3 mW cm^{-3} along with good stability.

2. Experimental Section

Preparation of plasma treated Fe_2O_3 nanorods. FeOOH nanorods were first synthesized by hydrothermal reacting $0.4 \text{ g FeCl}_3 \cdot \text{H}_2\text{O}$ with $0.24 \text{ g Na}_2\text{SO}_4$ at 120°C for 6 h using carbon cloth as substrate. The Fe_2O_3 nanorods on carbon cloth were obtained by thermal annealing the FeOOH precursor at 450°C in air for 3 h . The resulted porous Fe_2O_3 nanorods were then subjected to PH_3 plasma activation at 300°C for 1 h to get PH_3 activated Fe_2O_3 ($\text{Fe}_2\text{O}_3\text{-P}$) nanorods. The conditions used for plasma activation were a PH_3/He (1:9 in volume) flux of 50 sccm , a power of 200 W and a base pressure of 800 mTorr .

Preparation of MnO_2 nanosheets. The MnO_2 nanosheets were prepared on a carbon cloth by electrodeposition at 1.0 V for 2 min using 0.1 M manganese acetate and 0.1 M sodium sulfate as electrolyte. The electrodeposition was performed using a three-electrode configuration, where a Pt plate was used as the counter electrode, an Ag/AgCl electrode as the reference electrode and a carbon cloth as the working electrode.

Material characterization. X-ray diffraction (XRD) measurements were performed using

a Bruker D8 Advanced X-ray diffractometer using Cu K α radiation. Rietveld XRD refinement was performed using the MAUD program (Materials Analysis Using Diffraction).[41] Raman spectra were recorded on a Horiba LabRAM HR spectrometer. X-ray photoelectron spectroscopy (XPS) data were collected using an Amicus ECSA 3400 spectrometer. The morphology and structure were characterized using a FEI Nova Nano 630 scanning electron microscopy (SEM) and a FEI Titan 80-300ST (300 kV) transmission electron microscopy (TEM). Energy-filtered TEM (EFTEM) mode of TEM was utilized to generate the elemental maps. These experiments were completed by using a post-column energy-filter of model GIF Quantum 966 from Gatan, Inc. We selected energy-loss edges P-L23 (132 eV), O-K (532 eV), and Fe-L23 (708 eV) for the generating the maps of P, O, and Fe, respectively. Moreover, the so-called 3-window method was employed during the mapping experiments. Electron paramagnetic resonance (EPR) spectra were recorded using continuous wave Bruker EMX PLUS spectrometer equipped with standard resonator at room temperature employing 25 dB microwave attenuation with 5G modulation amplitude and 100 kHz modulation frequency. The UV-*vis* spectra were recorded using a Perkin Elmer Lambda 45 spectrophotometer and Teflon-stopped quartz cells with a path length of 1 cm.

Electrochemical measurements. The electrochemical studies of individual electrodes were carried out in 1 M Na₂SO₄ electrolyte using a three-electrode configuration, where a Pt wire and a Ag/AgCl electrode serve as counter electrode and reference electrode, respectively. Whereas for full cell measurements, 1 M Na₂SO₄ was used as electrolyte; Fe₂O₃-P and MnO₂ on carbon cloth were used as the negative electrode and positive electrode to assemble an asymmetric supercapacitor (ASC), respectively. The area of two electrodes was optimized prior to the fabrication of ASC according to the following equation:

$$C_+ A_+ V_+ = C_- A_- V_- \quad (2)$$

where A is the area, C the areal capacitance and V the voltage window for the positive (+)

and negative (-) electrodes, respectively. For a typical device, the stack thickness is ~0.8 mm. Cyclic voltammetry (CV), galvanostatic charge-discharge (GCD) tests, and electrochemical impedance spectroscopy (EIS) measurements were conducted on a Bio-Logic VMP3 potentiostat.

Calculations. The energy density was calculated from the GCD curves as following:

$$E = \frac{I \int V(t) dt}{Vol} \quad (3)$$

where I is the constant current for charge-discharge, V the voltage window, t the discharge time, Vol the total volume of the entire asymmetric supercapacitors. The power density was calculated according to

$$P = E/t \quad (4)$$

The capacitance can be calculated as

$$C = 2E/V^2 \quad (5)$$

3. Results and discussion

The Fe₂O₃ nanorod arrays on carbon cloth were first synthesized by thermally annealing FeOOH precursor (see Fig. S1 and Experimental section in Supporting Information) at 450 °C for 2.5 h. Scanning electron microscopy (SEM) and transmission electron microscopy (TEM) observation reveal that the as-obtained Fe₂O₃ inherits the morphology of FeOOH with dense nanorods around 65 nm in diameter vertically aligned on the skeleton of carbon cloth (Fig. 1a and b). High-resolution TEM (HRTEM) image further confirms the phase as the lattice spacing of 0.27 nm matches well with the d -spacing of (10-14) planes of Fe₂O₃ (Fig. 1c). The selected area electron diffraction (SAED) pattern further confirms the phase of the as-obtained nanorods (Fig. S2, Supporting Information). The Fe₂O₃ nanorods were then subjected to a PH₃ plasma activation for 1 h to get the Fe₂O₃-P nanorods. As shown in Fig. 1d,

the nanorod morphology is well retained after the plasma process while the carbon cloth turns black (bottom of Fig. 1d), indicating the bandgap of the material has changed. This is further confirmed by the UV-*vis* measurement, which shows that the bandgap of the pristine Fe_2O_3 decreases from 2.25 to 1.80 eV after plasma treatment (Fig. S3, Supporting Information). TEM image further reveals the porous nanorod morphology (Fig. 1e). A close observation shows that there is a ~ 1.8 nm thick amorphous layer on the surface (the crystalline-amorphous interface is indicated by a dash line, see Fig. 1f), which consists of Fe phosphide/phosphate as will be discussed later. The energy dispersive X-ray spectroscopy (EDS) line scan profiles (inset of Fig. 1e) further confirm the existence of Fe, O, and P in the nanorods. The electron energy loss spectroscopy (EELS) elemental maps (Fig. 1g) clearly indicates a P-rich surface layer that could be metal phosphide/phosphate. However, the lattice spacing of 0.27 nm (Fig. 1h) for Fe_2O_3 -P as well as the SAED pattern (Fig. 1i, see Fig. S4, Supporting Information for the selected area that was used for the diffraction imaging) reveal that the phase remains Fe_2O_3 , which suggests that the plasma activation does not change the bulk material. The plasma activation also introduces abundant of defects such as line dislocations (Fig. 1j), which would provide more active sites for electrochemical reactions.[42]

Fig. 1. Morphological characterization of Fe_2O_3 and $\text{Fe}_2\text{O}_3\text{-P}$ nanorods. (a) SEM image and digital photograph, (b) TEM, and (c) HRTEM images of Fe_2O_3 nanorods. (d) SEM image and digital photograph, (e,f) TEM images, (g) EELS elemental maps, (h) HRTEM image, (i) SAED pattern of $\text{Fe}_2\text{O}_3\text{-P}$ nanorods, and (j) Inverse Fourier-filtered image of the square marked area in h. The inset of e shows the EDS line scan of elemental signal profiles.

We further carried out structural characterizations of Fe_2O_3 and $\text{Fe}_2\text{O}_3\text{-P}$ nanorods. The X-ray diffraction (XRD) patterns of these two samples can be indexed into the hexagonal hematite phase (Fig. 2a), again confirming no phase transformation during the plasma process. We noted that there are two small diffraction peaks around 31° and 55° are observed in both samples, which should be from the $\gamma\text{-Fe}_2\text{O}_3$ (#25-1402) formed during the thermal annealing. Though the XRD patterns are identical, the cell parameters obtained from Rietveld XRD refinements are sensibly different from each other (Fig. S5, Supporting Information). This result suggests that the plasma treatment has affected the crystal structure of Fe_2O_3 . The EDS spectra show that P is introduced to the Fe_2O_3 after plasma activation (Fig. 2b), which might

mainly exist on the surface as iron phosphates and phosphides as revealed by X-ray photoelectron spectroscopy (XPS) analysis. For pristine Fe_2O_3 , the Fe 2p spectrum shows two distinguished peaks ($2p_{3/2}$ at 711.0 eV and $2p_{1/2}$ at 724.6 eV, $\Delta = 13.6$ eV) along with their associated satellite peaks (Fig. 2c), which match well with those reported for hematite.[43, 44] Whereas for $\text{Fe}_2\text{O}_3\text{-P}$, peak fitting analysis suggests two new distinct iron species, which can be identified Fe^{3+} in phosphates (Fe-PO_4 , $2p_{3/2}$ peak at 713.6 eV) and $\text{Fe}^{\delta+}$ (δ is likely very close to 0) in phosphides (Fe-P , $2p_{3/2}$ peak at 707.7 eV), respectively.[37] Further, the P 2p spectrum of $\text{Fe}_2\text{O}_3\text{-P}$ (Fig. 2d) also suggests the existence of P^{5+} (Fe-PO_4) and $\text{P}^{\delta-}$ (Fe-P),[45] in agreement with our TEM observation (see Fig. 1f and h). To probe the effects of plasma activation on the properties of $\text{Fe}_2\text{O}_3\text{-P}$, we then performed electron paramagnetic resonance (EPR) analysis, a technique that is sensitive to unpaired electrons and has been used to reveal the concentration of O vacancies in Fe_2O_3 . [21] As shown in Fig. 2e, the EPR spectra of both Fe_2O_3 and $\text{Fe}_2\text{O}_3\text{-P}$ show a main signal at $g = 2.0$, which can be assigned to Fe^{3+} ions coupled by exchange interactions.[46, 47] Compared to Fe_2O_3 , the EPR spectrum of $\text{Fe}_2\text{O}_3\text{-P}$ is much broader, suggesting that there are interactions between Fe^{3+} and other low valance Fe species (e.g., $\text{Fe}^{\delta+}$). The peak intensity is also much higher, which indicates more O vacancies (defects) present in $\text{Fe}_2\text{O}_3\text{-P}$. [21] Raman spectra were also collected and all the Raman peaks can be indexed to $\alpha\text{-Fe}_2\text{O}_3$ (Fig. 2f). Note that a negative shift in peaks for $\text{Fe}_2\text{O}_3\text{-P}$ is observed, suggesting an increased concentration of O vacancies. Similar phenomenon has also been reported for N_2 -annealed Fe_2O_3 . [21] Further, an induced strain between surface longer Fe-P bonds and Fe-O is expected (an average length of 2.369 Å for Fe-P bonds compared to 2.009 Å for Fe-O bonds). The lengthening of the interionic distance is correlated to a decrease of the force constants between pairs of ions, also results in a negative shift. These results further demonstrate that the plasma activation doesn't change the main phase of bulk Fe_2O_3 , but creates more O vacancies (defects), which would improve the intrinsic conductivity and promote the reactivity of Fe_2O_3 . Moreover, the *in situ* generated surface phosphates and

phosphides could also increase the effective surface area and participates in the surface faradaic reactions as will be demonstrated later.

Fig. 2. Structural characterization of Fe_2O_3 and $\text{Fe}_2\text{O}_3\text{-P}$ nanorods. (a) XRD patterns, (b) EDS spectra, and (c) Fe 2p XPS spectra of Fe_2O_3 and $\text{Fe}_2\text{O}_3\text{-P}$. (d) P 2p XPS spectrum of $\text{Fe}_2\text{O}_3\text{-P}$ nanorods. (e) EPR spectra and (f) Raman spectra of Fe_2O_3 and $\text{Fe}_2\text{O}_3\text{-P}$. The inset of f shows the zoom-in Raman spectra of the marked area.

We thus studied the electrochemical performance of Fe_2O_3 and $\text{Fe}_2\text{O}_3\text{-P}$ using a three-electrode configuration in 1 M Na_2SO_4 electrolyte. Fig. 3a compares the cyclic voltammograms (CVs) of carbon cloth, Fe_2O_3 , and $\text{Fe}_2\text{O}_3\text{-P}$ recorded at 100 mV s^{-1} . As expected, the $\text{Fe}_2\text{O}_3\text{-P}$ electrode exhibits a substantially higher current density than that of pristine Fe_2O_3 electrode, indicating a great enhancement in pseudocapacitive performance due to the plasma activation. The quasi-rectangular shape further suggests that the $\text{Fe}_2\text{O}_3\text{-P}$ electrode is charged/discharged at a pseudo-constant rate over the entire voltammetric cycles with a rapid faradaic reaction between alkaline cations (e.g., Na^+ , Li^+). [48, 49] Such phenomenon is likely due to improved conductivity and the fast diffusion of ions during

charge-discharge process.[50] The CV for Fe₂O₃-P retains the rectangular shape even at 200 mV s⁻¹ (Fig. S6, Supporting Information), implying an ideal capacitive performance. Fig. 3b displays the galvanostatic charge-discharge (GCD) profiles of Fe₂O₃, and Fe₂O₃-P electrodes collected at 2 mA cm⁻² (see Fig. S6, Supporting Information for GCD profiles at different current densities). Larger covered area can be identified for Fe₂O₃-P, suggesting a higher capacitance. Indeed, the Fe₂O₃-P can deliver a much higher areal capacitance of 340 mF cm⁻² (369 F g⁻¹) at 1 mA cm⁻², compared to 66 mF cm⁻² (86 F g⁻¹) of pristine Fe₂O₃ (Fig. 3c). Note that this capacitance is considerably higher than that reported for most Fe₂O₃-based anodes, such as Fe₂O₃ nanotubes (180 mF cm⁻² at 1 mA cm⁻²),[14] oxygen-deficient Fe₂O₃ nanorods (277 mF cm⁻² at 10 mV s⁻¹),[21] Fe₂O₃@PANI nanowires (~52 mF cm⁻² at 1 mA cm⁻²),[16] Fe₂O₃@PPy nanotubes (207 mF cm⁻² at 1 mA cm⁻²),[20] and Fe₃O₄@Fe₂O₃ nanorods (232 F g⁻¹ at 5 mV s⁻¹)[18] (Table S1, Supporting Information). The Fe₂O₃-P anodes also possess a good cycling stability with 83% capacitance retention after 5,000 cycles at a high current density of 20 mA cm⁻² (Fig. 3d). The SEM characterization after cycling shows that the overall nanorod morphology remains (Fig. S7, Supporting Information). The EDS spectrum and the EELS elemental mapping further reveal the existence of Fe, O, and P, suggesting the surface phosphide/phosphate layer is stable at least for 5000 cycles of electrochemical test. These results confirm the efficacy of our strategy for greatly enhancing the performance of Fe₂O₃ anodes through surface plasma activation.

Fig. 3. Comparison of electrochemical performance of Fe₂O₃ and Fe₂O₃-P nanorods in 1 M Na₂SO₄. (a) CV curves at a scan rate of 100 mV s⁻¹. (b) CD profiles at a current density of 2 mA cm⁻². (c) Capacitance plotted against current density. (d) Cycling performance at 20 mA cm⁻². (e) Nyquist plots. (f) Difference in current density plotted against scan rate showing the extraction of the double-layer capacitance.

In an effort to understand the origin of the greatly enhanced performance, we first carried out the electrochemical impedance spectroscopy (EIS) analysis. The result reveals that the charge transfer resistance of Fe₂O₃-P is much smaller than that of Fe₂O₃ (Fig. 3e), indicating the improved conductivity of Fe₂O₃ after plasma activation. The abundant O vacancies (see Fig. 1e) not only improve the conductivity but also provide additional active sites for redox reactions.[21] Further, the plasma treatment has introduced phosphates/phosphides to the surface. The partial replacement of O with P on the surface would result in a system with less number of electrons, hence shifting the fermi level to valence bands, which leads to a narrower bandgap, i.e., an improved conductivity (please also see the UV-vis spectra in Fig. S3). We also measured the double layer capacitances (C_{dl}) and estimated the electrochemically active surface areas (ECSAs) of the electrodes (CV curves used for the

estimation of C_{dl} can be found in Fig. S8, Supporting Information).[51, 52] The result shows that the ECSA of Fe_2O_3 -P is 8 times larger than that of Fe_2O_3 (Fig. 3f). Such dramatic increase in effective surface area would promote the ion diffusion and provide more active sites. Further, it is noted that the reactivity of electrode materials is associated with the chemical bonds and electronic environments.[53] The covalent-ionic bond character can be evaluated according to following equation:

$$\text{Covalent character (\%)} = \exp[-0.25(X_a - X_c)^2] \quad (1)$$

where X_a and X_c represent electronegativity value of anion and cation, respectively. Therefore, the covalent characters of Fe-O and Fe-P can be calculated as 52.3% and 96.7%, respectively ($X_{Fe} = 1.83$, $X_P = 2.19$, and $X_O = 3.44$). The high covalency degree of Fe_2O_3 -P suggests the electrons in 3d orbitals of Fe have higher energies. Further, as we discussed earlier, the Fe-P bonds are generally longer than that of Fe-O bonds, together with the high covalency degree, the activation energy barrier for the redox reactions would be much smaller than that for pristine Fe_2O_3 , leading to an enhanced surface reactivity. It is also worth mentioning that Ni/Co phosphates and phosphides have already shown good electrochemical performance as SC electrodes.[38, 54-56] It is expected that Fe phosphates/phosphides are also involved in the surface faradaic reactions and contribute to the performance. It is worth mentioning that such Fe phosphates/phosphides layer is ultrathin (~ 1.8 nm, see Fig. 1f) and is thus expected not to have significant activity for HER. Indeed, an increase in surface Fe phosphates/phosphides amount, e.g., by prolonging the plasma activation time, leads to worse capacitive performance as the operational potential window is narrowed due to the strong hydrogen evolution catalyzed by Fe phosphides (Fig. S9, Supporting Information).[57, 58] Interestingly, the plasma treated carbon cloth shows almost the same performance as the pristine one (Fig. S10, Supporting Information), further confirming the enhancement we observed in Fe_2O_3 -P should be due to the synergy between Fe and P as we discussed earlier.

These results suggest that the plasma activation could serve as an effective and efficient strategy for enhancing the pseudocapacitive performance of Fe_2O_3 anodes.

Encouraged by the high performance achieved on Fe_2O_3 -P anodes, we further assembled ASC devices using Fe_2O_3 -P and MnO_2 nanosheets as negative and positive electrodes, respectively. The MnO_2 nanosheet arrays were synthesized by electrodeposition and can deliver a capacitance of 221 mF cm^{-2} at 1 mA cm^{-2} in $1 \text{ M Na}_2\text{SO}_4$. The detailed characterization of MnO_2 nanosheets can be found in Fig. S11, Supporting Information. Prior to assembling the ASCs, the charges between Fe_2O_3 -P and MnO_2 electrodes are balanced and the optimized areal ratio is about 1:1.5 (see Fig. 4a and details in experimental section, Supporting Information). Fig. 4b displays the CV curves of Fe_2O_3 -P// MnO_2 ASC device recorded at different scan rates from 10 – 200 mV s^{-1} within the voltage window of 0 – 1.6 V . All the CV curves present a quasi-rectangular shape and are highly symmetric, reflecting a good reversibility and typical capacitive behavior. The symmetric GCD profiles with triangular shapes further confirm the superior capacitive performance of our assembled ASC devices (Fig. 4c). We further calculated the energy density and power density of our devices and the results are summarized as Ragone plots in Fig. 4d and e. Impressively, our Fe_2O_3 -P// MnO_2 ASC device can achieve a high stack energy density (based on the volume of entire device) of 0.42 mWh cm^{-3} at a stack power density of 10.3 mW cm^{-3} , corresponding to a gravimetric energy density of 57.3 Wh kg^{-1} at 1404 W kg^{-1} , and can still maintain 0.14 mWh cm^{-3} (19.5 Wh kg^{-1}) at 258.1 W cm^{-3} ($35,097 \text{ W kg}^{-1}$). Though the device performance may vary with the electrode material preparation methods and the electrochemical testing conditions, the activity of our devices outperforms most of the recently reported iron oxides-based ASCs under similar testing conditions (see comparison in Fig. 4d,e). Besides the high energy and power densities, our Fe_2O_3 -P// MnO_2 ASC also shows good cycling performance with 88% capacitance retention after 9000 cycles at a high current density of 10 mA cm^{-2} (Fig. 4f).

4. Conclusion

In summary, we have presented a new PH₃ plasma activation strategy to significantly boost the capacitive performance of Fe₂O₃ anodes for high-performance ASCs. The plasma treatment doesn't change the bulk phase of Fe₂O₃, however, it effectively tunes the conductivity, active surface area, and defects concentration. As a result, a *fivefold* enhancement in areal capacitance is achieved for the plasma functionalized Fe₂O₃ (340 mF cm⁻² at 1 mA cm⁻²) when compared with the pristine Fe₂O₃ (66 mF cm⁻²). The capacitance of Fe₂O₃-P is among the highest numbers reported for Fe₂O₃ electrodes. Furthermore, the ASC

devices consist of $\text{Fe}_2\text{O}_3\text{-P}$ and MnO_2 electrodes achieve a high stack energy density of 0.42 mWh cm^{-3} (57.3 Wh kg^{-1}) at a stack power density of 10.3 mW cm^{-3} (1404 W kg^{-1}) along with good stability, outperforming most of the iron oxides-based ASCs. The new plasma activation may serve as a general strategy for enhancing the electrochemical performance of oxides in supercapacitors and many other applications.

TOC

Author Biographies

Hanfeng Liang received his PhD in applied chemistry in 2015 from Xiamen University. As a visiting graduate student, he studied at University of Wisconsin-Madison from 2013-2015. He is currently a postdoc in Prof. Husam Alshareef's group at KAUST. His current research focuses on rational growth of nanomaterials and their applications.

Chuan Xia is currently a PhD candidate of the Materials Science and Engineering program at KAUST. His research interests focus on the development of nanostructured chalcogenides and their applications.

Abdul-Hamid Emwas received a MSc in Biophysical Chemistry University of Bergen and a PhD in Physical Chemistry from University of New Brunswick. Currently he is a research scientist at NMR Core Lab of KAUST. Before that he worked at the Miami University, USA, CRUK Institute for Cancer Studies, and University of Waterloo.

Dalaver H. Anjum received his PhD Physics in 2002 from the University at Albany-State University of New York. Currently he is a Sr. Scientist in the Imaging and Characterization Lab of KAUST. In this capacity, he is performing materials characterization by utilizing TEM. He performs the imaging, diffraction, elemental analyses of materials to determine their structure-property relationships. He has authored/co-authored over 180 publications related to the field of materials characterization by using TEM.

Xiaohe Miao received a PhD Degree from Zhejiang University and was a postdoctoral fellow in KAUST Catalysis Center in 2010-2014. Currently she is staff scientist in Imaging and Characterization Core Lab of KAUST. Her research interests focus on the design, synthesis and structure determination of metal-organic frameworks (MOFs) for the applications of heterogeneous/homogeneous catalysis, gas separation and energy storage/conversion.

Husam N. Alshareef is a Professor of Materials Science & Engineering at King Abdullah University of Science & Technology (KAUST). He obtained his PhD at North Carolina State University, USA. Following nearly 10 years of experience in the semiconductor industry, he joined KAUST in 2009. His group is interested in developing semiconductor nanomaterials for electronics and energy applications.

Highlights

- PH_3 plasma activation simultaneously creates atomic-scale defects and nanoscale porosity of Fe_2O_3 .
- Plasma activated Fe_2O_3 delivers a much higher capacitance than pristine Fe_2O_3 .
- High performance asymmetric supercapacitors based on plasma activated Fe_2O_3 and MnO_2 were assembled.
