Metal Halide Perovskites for Solar-to-Chemical Fuel Conversion

Jie Chen, Chunwei Dong, Hicham Idriss, Omar F. Mohammed, and Osman M. Bakr*

This review article presents and discusses the recent progress made in the stabilization, protection, improvement, and design of halide perovskite-based photocatalysts, photoelectrodes, and devices for solar-to-chemical fuel conversion. With the target of water splitting, hydrogen iodide splitting, and CO₂ reduction reactions, the strategies established for halide perovskites used in photocatalytic particle-suspension systems, photoelectrode thin-film systems, and photovoltaic-(photo)electrocatalysis tandem systems are organized and introduced. Moreover, recent achievements in discovering new and stable halide perovskite materials, developing protective and functional shells and layers, designing proper reaction solution systems, and tandem device configurations are emphasized and discussed. Perspectives on the future design of halide perovskite materials and devices for solar-to-chemical fuel conversion are provided. This review may serve as a guide for researchers interested in utilizing halide perovskite materials for solar-to-chemical fuel conversion.

1. Introduction

Efficient conversion of solar energy to chemical fuels on a scale on par with the energy supplied from conventional fossil fuels is a promising yet challenging pathway to realizing a sustainable carbon-neutral society.^[1–7] The main chemical energy carriers in this pathway are H₂ and various C₁–C₃ compounds, which have either high energy densities or versatile applications in industry but require thermodynamically uphill water splitting or CO₂ reduction reactions to be produced.^[5–9] To date, several solar-to-chemical fuel conversion systems, including photocatalyst particle-suspension, photoelectrode thin-film, and photovoltaic (PV)-electrocatalysis systems, have been

developed to meet the requirements of certain reactions and have been optimized for practical use.^[5,8] Although the reaction system configurations vary, one of the key elements to a solar-to-chemical fuel conversion system is the semiconductor material, which converts solar energy to excited electrons and holes that then separate to drive uphill reduction and oxidation reactions.^[2,10,11]

Metal halide perovskites with a general formula of ABX₃ (Figure 1a), where typically A is methylammonium (MA), formamidinium (FA) or Cs; B is Pb or Sn; and X is Cl, Br or I, have recently emerged as a promising class of high-performance semiconductors since the first solar cell involving MAPbI₃.^[12] These perovskites have remarkable photophysical, optical, and transport properties, such as long charge carrier lifetimes and low trap densities,^[13,14] long electron and hole diffusion lengths,^[15–17] large absorption coefficients,^[18,19] and a widely tunable bandgap that enables light harvesting from UV to near IR spectral range^[20,21] (Figure 1b). More importantly, the band positions of most halide perovskites satisfy the thermodynamic requirements for water and CO₂ reduction, as shown in Figure 1c.

By virtue of their impressive photophysical properties, halide perovskites have been successfully used in various optoelectronic devices, including solution-processed solar cells with power conversion efficiency (PCE) exceeding 25%,^[22–25] low-threshold lasers,^[26,27] bright light-emitting diodes^[28–30] and sensitive photo- and X-ray detectors.^[31–34] These successes have also motivated the development of solar-to-chemical fuel conversion systems based on halide perovskites. However, halide perovskites generally have low formation enthalpy, which intrinsically makes them easy to form as well as easy to be damaged.^[35] Upon an external stimuli such as moisture and polar solvent, oxygen, heat, and irradiation, halide perovskites are easily decomposed to its binary halide components (for example, MAPbI₃ → MAI + PbI₂). This instability of halide perovskites has limited their study and applications. To date, substantive efforts have been made to enable halide perovskites for solar-to-chemical fuel conversion. For example, halide perovskites powder suspensions were used in non-aqueous solutions for CO₂ reduction.^[36] Moreover, halide perovskite photoelectrodes were protected by functional layers for H₂O reduction^[37] and CO₂ reduction.^[38] In another instance, perovskite photovoltaics were used to drive electrocatalytic water splitting or CO₂ reduction by connecting an isolated photovoltaic

cell to an electrocatalysis cell.^[8] Despite this progress, the field is at its infancy and there is still much room for innovation in designing target reaction systems as well as in enhancing the stability and efficiency of halide perovskites for solar-to-chemical fuel conversion.

In this review, we summarize the advancements made to date in the development of halide perovskites for solar-to-chemical fuel conversion. The reactions involved in this process are water splitting, hydrogen iodide splitting, and CO₂ reduction. We classify and introduce the achievements made in incorporating halide perovskites into photocatalyst particle-suspension systems, photoelectrode thin-film systems, and photovoltaic-(photo)electrocatalytic systems. We also introduce and discuss the syntheses and modification strategies established for yielding stable and efficient halide perovskites as well as the design of reaction system configurations. We hope that this work will inspire researchers to translate the benefits afforded by the remarkable photophysical properties of halide perovskites into highly efficient, stable, and selective solar-driven chemical fuel production.

2. Photocatalytic Particle-Suspension Systems

In 1979, Bard designed the first photocatalyst particle-suspension system for water splitting^[39] after Fujishima and Honda had discovered the Honda–Fujishima effect in the early 1970s.^[40] A photocatalytic reaction is carried out in a closed gas-circulation cell containing semiconductor particles as the photocatalysts, water as the proton or oxygen source, sacrificial reagents (if necessary) for half oxidation or reduction reactions, and dissolved CO₂ (if the system is meant for CO₂ reduction).

Upon light irradiation, a semiconductor photocatalyst generates charge carriers (electrons and holes), see process (1) in **Figure 2**. Here, the energy of the incident light must exceed the bandgap energy of the semiconductor to allow for effective excitation. As the ΔG^0 values for water splitting and CO₂ reduction are 237 and 259 kJ mol⁻¹ (taking the conversion of CO₂ to CO as an example), respectively, a theoretical bandgap of at least 1.34 eV (corresponds to 954 nm) is required. Photo-excited charge carriers then migrate to the reactive sites for certain reactions, as shown in process (2) of **Figure 2**. Concomitant recombination, including bulk and surface recombination, process (2'), of the charge carriers (electron and hole) will also occur radiatively and/or nonradiatively, releasing photons or thermal energy. The electrons and holes reaching the reactive sites then undergo an electrochemical catalytic process to produce chemical fuels. Thermodynamically, such a process requires the electron potential (conduction band, CB potential of the semiconductor) to be more negative than 0 V versus normal hydrogen electrode (NHE) for reducing H⁺ to H₂ (−0.107 V vs NHE for CO₂ to CO, pH = 0), and the hole potential (valence band, VB potential) must be more positive than the oxidation potential of H₂O/O₂ (1.23 V vs NHE, pH = 0). Generally, halide perovskites thermodynamically favor both the reduction and oxidation reactions, as their CB and VB straddle the water/CO₂ reduction and water oxidation potentials (**Figure 1c**). However, the complexity of the overall catalytic cycle requires the use of multiple components for kinetic reasons in addition

Jie Chen obtained his bachelor degree in Applied Chemistry from Xi'an Jiaotong University in 2011 and his Ph.D. degree in Power engineering and engineering Thermophysics from Xi'an Jiaotong University in 2017. During 2015–2017, he worked as a joint student in Department of Chemistry at UW-Madison. He is currently a postdoctoral researcher working with Prof. Osman Bakr in the KAUST Catalysis Center. His research interests focus on functional nanomaterials for catalysis and optoelectronics applications.

Chunwei Dong obtained his bachelor degree in Chemistry from Jilin University in 2013 and his Ph.D. degree in Polymeric Chemistry and Physics under the supervision of Prof. Hao Zhang from Jilin University in 2018. He is currently a postdoctoral researcher working with Prof. Osman Bakr in KAUST Catalysis Center. His research interests focus on the synthesis of functional nanomaterials for catalytic applications.

Osman M. Bakr holds a B.Sc. in Materials Science and Engineering from MIT (2003) as well as M.S. and Ph.D. in Applied Physics from Harvard University (2009). He is currently Professor of Materials Science and Engineering at KAUST, Saudi Arabia. His research group focuses on the study of hybrid organic–inorganic materials; particularly, advancing their synthesis and self-assembly for applications in optoelectronics and catalysis.

to the above basic thermodynamic requirement in a real-experimental scenario. In this case, electrocatalysts (ECs) such as Pt, MoS₂, RuO₂, and others are usually needed to extract electrons/holes from the semiconductors, as well as to promote the kinetics for the catalytic reactions.

For photocatalyst particle-suspension systems, water/moisture instability issues associated with halide perovskites must be considered. Halide perovskites generally cannot resist water, even though some strategies can render them stable against a certain percentage of humidity.^[41,42] To this end, researchers have expended great efforts by developing water-stable perovskite and structures, discovering proper proton sources (e.g.,

hydrogen iodide, HI) other than water, and dispersing halide perovskite in non-aqueous solutions for CO₂ reduction.

2.1. Water-Stable Halide Perovskites and Structures

Most of the reported halide perovskites have been recognized to dissolve like a salt in water. Encouragingly, Ju et al. have reported that DMASnI₃ (DMA = CH₃NH₂CH₃⁺), although not in a typical 3D perovskite structure, can be suspended in deionized (DI) water for photocatalytic water splitting H₂ production with a rate of 0.64 μmol h⁻¹ (200 mg catalysts) for at least 5 h (Figure 3a).^[43] This is an interesting work in which a halide perovskite has been reported to for water splitting, although the precise mechanism underlying this water stability is not yet clear. ADPb₂Cl₅ (AD = acridine), with a bandgap of 2.06 eV, was also reported to be water-stable; however, the material was not used for solution-phase photocatalytic reactions.^[44] ADPb₂Cl₅ is stable because the large steric hindrance exhibited by AD cations distributed between the rigid lead chloride inorganic matrices could effectively prevent erosion by water.

Strategies for protecting and functionalizing halide perovskites for photocatalysis have also been developed. One instant idea is to coat perovskite nanocrystals with a shell that is water-resistant, stable, and photocatalytically active. Li et al. have coated colloidal CsPbBr₃ with a TiO₂ shell by hydrolysis

and calcination of a titanium precursor (Figure 3b).^[45] The CsPbBr₃@TiO₂ NCs were very stable and exhibited excellent water stability for more than 12 weeks, with size, morphology, and crystallinity unchanged. Remarkably, the CsPbBr₃@TiO₂ NCs maintained a relatively constant photocurrent over 8 h under real-world photoelectric test conditions in water (Figure 3c). Using a zeolitic imidazolate framework (ZIF) as the shell, Kong et al. have fabricated CsPbBr₃@ZIF core-shell structures by in situ growth of ZIF on CsPbBr₃ quantum dots (QDs).^[46] The CsPbBr₃@ZIF composites were active and stable for the photocatalytic CO₂ reduction in the presence of CO₂ and H₂O vapor and exhibited electron consumption rates of 15.5 and 29.6 μmol g⁻¹ h⁻¹ for CsPbBr₃@ZIF-8 and CsPbBr₃@ZIF-67, respectively. Other perovskite@shell structures, such as CsPbBr₃@SiO₂^[47] and CsPbBr₃@Al₂O₃,^[48,49] have also been successfully synthesized; however, they have not been used as described above and might not be active for photocatalytic reactions because the SiO₂ or Al₂O₃ layers are not photocatalytic active.

2.2. Using Hydrogen Iodide (HI) Solution Other than Water

HI was first pointed out by Park et al. as a better choice than water for providing protons for H₂ production when employing MAPbI₃ as the photocatalyst.^[50] MAPbI₃ is stable in a MAPbI₃-saturated aqueous HI solution because of the dynamic equilibrium between MAPbI₃ and HI. By dissolving a series of amounts of MAPbI₃ in HI, Park et al. obtained corresponding solubility data and proposed a dynamic equilibrium model for the MAPbI₃ to be stable in HI solution (Figure 4a,b). Moreover, the authors identified the conditions for the formation of stable MAPbI₃ precipitates in aqueous solution by controlling the I⁻ and H⁺ concentrations ([I⁻] ≤ [H⁺], pH ≤ -0.5, -log[I⁻] ≤ -0.4). In aqueous HI solution, the MAPbI₃ powders could efficiently split HI into H₂ and I₃⁻ under visible-light irradiation according to a mechanism that is similar to water splitting (Figure 4c,d), and a solar HI splitting efficiency of 0.81% was achieved when using Pt as a cocatalyst.

HI solution has been widely adopted by other researchers since the work of Park et al. For example, Huang and co-workers used HI and HBr/HI mixed solutions to test a

modified MAPbI₃/rGO material^[51] and the mixed halide perovskites MAPbBr_{3-x}I_x^[52] and CsPbBr_{3-x}I_x.^[53] Remarkably, MAPbBr_{3-x}I_x/Pt exhibited a photocatalytic H₂ evolution rate of 651.2 μmol h⁻¹ (250 mg catalysts) under visible light (100 mW cm⁻², λ ≥ 420 nm) and a solar-to-chemical conversion efficiency of 1.05%. Similarly, Wang et al. found that a high concentration of MAPbBr₃ can be stable in an aqueous solution of HBr, which can be split into H₂ and Br₂.^[54] A high apparent quantum efficiency of ≈16.4% for H₂ evolution at 420 nm was achieved over their modified photocatalyst (Pt/Ta₂O₅-MAPbBr₃-PEDOT:PSS). It should be reminded that the Pb-X (X = Cl, Br, I) are also photoactive materials, which may also contribute to the photocatalytic HI splitting reaction. Detailed and in-depth investigation may be needed to further reveal the effect of the Pb-X complex when using halide perovskite nanocrystals for photocatalysis.

2.3. In Non-Aqueous Reaction Solutions

Non-aqueous solution systems with a trace amount or in the absence of water are designed for CO₂ reduction reactions using halide perovskites. Ethyl acetate was selected by Su and co-workers for CO₂ reduction using CsPbBr₃ QDs/GO because of its mild polarity and high CO₂ solubility.^[36] They reported that in ethyl acetate, CsPbBr₃ QDs catalyzed CO₂ reduction at an electron consumption rate of 23.7 μmol g⁻¹ h⁻¹ with a selectivity of over 99.3% for CO₂ reduction rather than for proton reduction. After compositing with GO, the rate of electron consumption increased by 25.5% because of the improved electron extraction and transport. Analogous solution systems have also been adapted to other types of halide perovskites, such as Cs₂AgBiBr₆^[55] and CsPbBr₃.^[36,56] Ou et al. reported that acetonitrile with a trace amount of water (0.3 vol%) can also serve as a reaction solution for photocatalytic CO₂ reduction over halide perovskites.^[57] The authors tested CsPbBr₃ QDs/g-C₃N₄ in acetonitrile/H₂O and achieved a 149 μmol g⁻¹ h⁻¹ CO production rate from CO₂ under visible-light irradiation. Wu et al. recently carried out the same reaction in ethyl acetate solution with a higher water content of 1.2 vol%.^[58] With CO₂ saturated in this medium, MAPbI₃@PCN-221(Fe_x) exhibited a total yield of 1559 μmol g⁻¹ over an 80 h reaction period for CO (34%) and

CH₄ (66%) production. Notably, this work quantitatively demonstrated that the oxidation product is O₂ that is originated from water oxidation rather than other products possibly from the oxidation of ethyl acetate in the CO₂-saturated ethyl acetate/water reaction solution.

The photocatalytic water or HI splitting and CO₂ reduction performance of halide perovskites is summarized in **Table 1**. The as-developed halide perovskite photocatalysts generally exhibit enough stability to withstand a photocatalytic test. However, the photocatalysts' efficiencies are still quite low, especially considering the remarkable photophysical properties halide perovskites possess. In addition, the conditions for the photocatalytic tests vary in different groups, thus making it difficult to fairly compare and evaluate the strategies researchers have applied to improve the efficiency. Therefore, we strongly suggest that the community follow standard test conditions and/or provide detailed experimental procedures for photocatalytic reactions. Moreover, it could be important to point out what are the other reaction products beside H₂ and the reduced CO₂ in a particulate photocatalysis system, because other reaction paths happened during photocatalysis could also contribute to producing the target product.^[59]

3. Photoelectrode Thin-Film Systems

The first demonstration of a photoelectrode thin-film system, also known as a photoelectrochemical (PEC) cell, was by

Fujishima and Honda in 1972 using a TiO₂ single-crystal wafer as the photoanode and Pt black as the cathode to split water under light irradiation and an applied bias.^[40] A typical photoelectrochemical cell consists of a working electrode (i.e., photoelectrode), a counter electrode and a reference electrode (**Figure 5**). A photoelectrode can be fabricated by coating or growing several well-defined layers, such as a semiconductor layer, an electron/hole transport layer, and an electrocatalytic layer, onto a conductive substrate. Figure 5 shows a cell structure in which the working electrode functions as a photocathode. In the cell, electrons from the photoexcited semiconductor are generated at the electrode for reduction reactions, whereas holes are at the counter electrode for oxidation reactions.

The photoelectrode structure greatly relieves the harsh stability requirements for halide perovskites used in aqueous solutions, as it is technically much easier to coat a water-impermeable, conductive, and even catalytic layer onto the well-defined halide perovskite layer than onto the solution-phase nanocrystals. In practice, researchers indeed choose essentially the same strategy, coating layers onto a halide perovskite, to create stable halide perovskite photoelectrodes. To date, many types of such layers have been implemented, including a Ni layer (8 nm),^[61] Field's metal (a fusible alloy that melts at ≈62 °C.),^[37] Ti foil,^[62] an In-Bi alloy layer^[38] and a mesoporous carbon/graphite sheet.^[63] In the following, we discuss these approaches by classifying them according to their target reactions, i.e., water oxidation, water reduction, and CO₂ reduction.

Table 1. Summary of the reported photocatalytic water or HI splitting and CO₂ reduction reactions using halide perovskites.

Materials	Reaction	Solution	Light source	Stability	Efficiency ^{a)}	Ref.
DMASnI ₃	H ₂ O red. to H ₂	DI water	300-W Xe lamp (full spectrum)	>5 h	3.2 μmol g ⁻¹ h ⁻¹	[43]

^{a)}For proton reduction, values pertain to the H₂ production rate; for CO₂ reduction, values pertain to the electron consumption rate unless otherwise noted. The rates were converted to μmol g⁻¹ h⁻¹; ^{b)}Oxygen was measured in these works but not quantified; ^{c)}Oxygen generated was measured and quantified.

3.1. Water Oxidation

Metal-based materials were first used to protect halide perovskite photoelectrodes. In 2015, Da et al. reported the first multi-layered MAPbI₃-based photoanode with an ultrathin Ni surface layer (8 nm) deposited by magnetron sputtering. The Ni layer functioned as both a physical passivation barrier and a hole-transferring catalyst for water oxidation (Figure 6a).^[61] Note that the surface of Ni was gradually converted to nickel oxide. The photoanode exhibited a photocurrent density of over 10 mA cm⁻² in 0.1 M Na₂S at 0 V versus Ag/AgCl under AM 1.5G simulated sunlight at 100 mW cm⁻². However, the photocurrent of

Figure 5. An illustration of a three-electrode photoelectrochemical (PEC) cell. The working electrode functions as a photocathode.

the photoanode could be maintained above 2 mA cm⁻² for only 15–20 min. Wang et al. applied this ultrathin Ni passivation strategy to their surface-functionalized MAPbI₃ and further improved the stability to ≈30 min, but the photocurrent density was reduced to 2.1 mA cm⁻².^[64] Building on this layered structure with Ni as the protective and catalytic layer, in 2016, Hoang et al. further used a dense hole-transport layer to enhance the stability of the MAPbI₃ photoelectrode.^[65] The device stability was increased from 15 min to more than 30 min. Later in 2018, Nam et al. have fabricated a more stable MAPbI₃ photoanode by introducing a low-melting-point Field's metal layer between the perovskite and Ni layers.^[66] The perovskite photoanode was found to be stable for 6 h at ≈13 mA cm⁻² under 0.7 Sun illumination and a bias of 1.3 V versus reversible hydrogen electrode (RHE) in potassium hydroxide solution (KOH) solution.

Carbon materials have also been employed as protective layers for halide perovskites. Tao et al. encapsulated a (5-AVA)_x(MA)_{1-x}PbI₃ [5-AVA = HOOC(CH₂)₄NH₃⁺]-based photoanode with conductive carbon paste and silver conductive paint for water oxidation.^[67] The photoanode achieved unprecedented stability, remaining stable in an alkaline electrolyte for more than 48 h. The material also showed a high photocurrent density of 12.4 mA cm⁻² at 1.23 V versus RHE in an alkaline electrolyte. This high stability was largely due to the coating of a thick carbon layer (several hundreds of micrometers) onto the halide perovskites. Very recently, Poli et al. used a commercial thermal graphite sheet and a mesoporous carbon scaffold to encapsulate a CsPbBr₃-based photoanode (Figure 6b).^[63] A record stability of 30 h in aqueous electrolyte with current above 2 mA cm⁻² at 1.23 versus RHE was achieved under constant simulated solar illumination. Furthermore, by functionalizing the surface of the graphite sheet with an Ir-based

Figure 6. a) Schematic illustration of photoelectrochemical test of a Ni-coated perovskite photoanode in a standard three-electrode system. water oxidation catalyst (WOC), the onset potential of the composite photoanode was cathodically shifted by 100 mV. Notably, $\approx 9 \mu\text{mol}$ of evolved O₂ were detected over a ≈ 130 min test using their TiO₂ | CsPbBr₃ | m-c | GS | WOC photoelectrode under continuous simulated solar light irradiation (AM 1.5G, 100 mW cm⁻²) in 0.1 M KNO₃ adjusted to pH 3.5 with H₂SO₄. This achievement marks by far the most stable and efficient halide perovskite photoanode for water oxidation.

3.2. Water Reduction

Field's metal is the most widely used protective and conductive layer since its first demonstration by the Reisner group as a coating onto a MAPbI₃-based photocathode for water reduction (Figure 7a).^[37] With Pt nanoparticles loaded as the hydrogen evolution electrocatalysts, the Reisner group obtained a record photocurrent density of 9.8 mA cm⁻² at 0 V versus RHE with an onset potential of 0.95 ± 0.03 versus RHE. The photoelectrode showed high stability, retaining more than 80% of its initial photocurrent for ≈ 1 h under continuous illumination (100 mW cm⁻², AM 1.5G, $\lambda > 400$ nm). The group further fabricated a tandem PEC system by coupling a Field's metal-protected cesium formamidinium methylammonium (CsFAMA) triple cation mixed halide perovskite photocathode with a stable BiVO₄/TiCo photoanode for bias-free solar-to-hydrogen (STH) production (Figure 7b).^[68] The perovskite photocathode alone could operate for up to 7 h with a photocurrent density of 12.1 ± 0.3 mA cm⁻² at 0 V versus RHE. After coupling with a BiVO₄ photoanode, the PEC tandem system, with a device

surface area of 0.25 cm², could operate for up to 20 h with a bias-free STH efficiency of $0.35 \pm 0.14\%$. Remarkably, because the fabrication method is highly reproducible, the tandem device could be scaled up to 10 cm² with only a slight drop in the photocurrent density. Also using Field's metal as the protective layer, Gao et al. fabricated an all-inorganic photocathode by incorporating CsPbBr₃ as the perovskite layer and NiO and ZnO as the hole and electron transport layers, respectively.^[69] This all-inorganic photocathode achieved a photocurrent of ≈ 1.2 mA cm⁻² at 0 V versus RHE and retained $\approx 94\%$ of its initial photocurrent after continuous illumination for 1 h (AM 1.5G).

Titanium foil is another good choice for protecting halide perovskite photoelectrodes. Zhang et al. fabricated a sandwich-like structure by pasting Ti foil onto a MAPbI₃-based photocathode (Figure 7c).^[62] With Pt loaded as the catalyst, this photocathode exhibited an onset potential at 0.95 V versus RHE and a photocurrent density of 18 mA cm⁻² at 0 V versus RHE, with an ideal ratiometric power-saved efficiency of 7.63%. Impressively, the photocathode retained good stability under 12 h of continuous illumination in water over a wide pH range.

3.3. CO₂ Reduction

One aim of CO₂ reduction is to alleviate the energy crisis and environmental issues by producing C₁–C₃ chemical fuels. The products of photoelectrocatalytic CO₂ reduction in aqueous media can be mixtures of formic acid, carbon

monoxide, formaldehyde, methane, and C₂–C₃ hydrocarbons. In this context, the goal of CO₂ reduction is to efficiently, stably, and selectively produce a target product. Thermodynamically, halide perovskites can drive CO₂ reduction reactions because they generally possess sufficiently negative conduction band potentials (Figure 1). However, CO₂ reduction using a halide perovskite-based photoelectrode has scarcely been reported. Encouragingly, Chen et al. recently demonstrated In–Bi alloy-coated MAPbI₃-based photocathodes for selective CO₂ reduction with nearly 100% faradaic efficiency (FE) for formic acid production in aqueous solution (Figure 8a).^[38] The In_{0.4}Bi_{0.6} composition was identified by a compositional screening strategy of a ternary In–Bi–Sn low melting-point alloy system. The photocathode was then fabricated by coating the catalytic, protective, and conductive In_{0.4}Bi_{0.6} alloy layer onto the halide perovskite. The photocathode operated at –0.6 V versus RHE under simulated AM 1.5G irradiation for more than 1.5 h (Figure 8b) and achieved a photo-assisted electrolysis system efficiency of 7.2%.

Studies detailing the use of halide perovskite-based photoelectrodes for water splitting and CO₂ reduction are

summarized in Table 2. As indicated, the as-developed halide perovskite photoelectrodes generally exhibit better stability than the photocatalysts, because the well-defined perovskite layers are well protected in the photoelectrodes. The overall performance (including stability and efficiency) of the photoelectrodes is quite promising, with the CsPbBr₃|mesoporous carbon|graphite sheet|Ir OER and (CsMAFA)PbI_xBr_{3–x}|FM|Pt–BiVO₄|TiCo designs considered the best for water oxidation and reduction, respectively. However, the photoelectrodes for CO₂ reduction have been rarely reported. Moreover, many works only demonstrated the photocurrent, which might not be a good criterion for evaluating the efficiency because the photocurrent can also originate from the corrosion of the electrodes or other side reactions. It is thus encouraged that the researchers report the solar to product conversion efficiency as well as the products in the future if possible. We believe that there is much more to be done regarding water splitting and selective CO₂ reduction to a target chemical fuel using halide perovskite photoelectrodes.

4. Perovskite Photovoltaics Integrated with (Photo)Electrocatalysis

Halide perovskite PVs can be aligned with a photoelectrode for wide-spectrum solar-to-chemical fuel conversion or can act as

an external circuit to power an electrocatalytic cell. A simplified illustration of a PV-integrated (photo)electrocatalytic system is shown in **Figure 9**, in which the PV absorbs light and provides the needed photovoltage for the both cathodic and anodic reactions to occur.

Table 2. A summary of the reported photoelectrodes using halide perovskites. FM: Field's metal; FE: faradaic efficiency; STH: solar-to-hydrogen efficiency.

Photoelectrode	Reaction	Electrolyte	Light source	Stability	Efficiency	Ref.
MAPbI ₃ Ni	H ₂ O Ox	0.1 M Na ₂ S	100 mW cm ⁻² , AM 1.5G	15–20 min	10 mA cm ⁻² @ 0 V vs Ag/AgCl	[61]

^{a)}Oxygen was measured and quantified in these works.

Figure 9. An illustration of a photovoltaic-integrated (photo)electrocatalysis system. The anode can also be photoactive in this case.

In a PV-PEC (where the electrodes are photoactive) or PV-EC system, the halide perovskite PV is isolated from the solution, acting as the photovoltaic power source for an unbiased solar-to-chemical fuel conversion device. In such devices, the halide perovskite-based photovoltaics can provide all the voltage needed to drive a water splitting or CO₂ reduction reaction without the help of an external power source. Halide perovskite PVs generally have large open-circuit voltages (1–1.4 eV). Therefore, two halide perovskite PV cells in tandem are enough to drive overall water splitting, whereas three cells in tandem are needed when using conventional Si and CIGS PVs. In addition, the cost of solution-processable halide perovskite PVs is much lower than that of Si or CIGS cells. In the following, we discuss the progress made in the development of PV-(photo)electrocatalysis systems.

4.1. Photovoltaic Integrated with Photoelectrocatalysis

In an integrated PV-PEC system, a photoanode or photocathode is connected in series to a halide perovskite PV. The photoanode(cathode) is often stacked on top of the halide perovskite PV because of its larger bandgap (>2 eV) than that of the halide perovskite. BiVO₄ is the most well-studied photoanode for water oxidation due to its suitable bandgap (2.4 eV) and superior PEC performance. In 2015, Kamat group demonstrated an all-solution-processed tandem water-splitting device composed of a cobalt phosphate (CoPi) catalyst-modified BiVO₄ photoanode and a single-junction MAPbI₃ perovskite solar cell.^[72] As shown in **Figure 10a**, the perovskite solar cell is placed under the BiVO₄ photoanode so that wavelengths >500 nm can pass through the BiVO₄ photoanode. To make full use of the lower-energy light in the bottom layer, the top layer should be highly transparent (**Figure 10b**, with BiVO₄ as the top layer). Because two modules are connected in series, the operating photocurrent density of a tandem PV-photoanode

device can be predicted from the intersection of the individual *J*-*V* curves (**Figure 10c**). This PV-photoanode device exhibited an STH efficiency of 2.5% at neutral pH without external bias (**Figure 10d**). Kim et al. applied a dual-doping strategy (hydrogen treatment and 3 at% Mo doping) to modify the BiVO₄ photoanode and then loaded cobalt carbonate (Co-Ci) as a catalyst. They further fabricated a MAPbI₃ PV-BiVO₄ photoanode tandem device with an STH efficiency of 4.3% in the wired configuration and 3.0% in the wireless configuration for a long stability test (12 h).^[73] Fe₂O₃ is another widely studied photoanode for halide perovskite PV-PEC tandem devices. Gurudayal et al. demonstrated that a MAPbI₃ solar cell in tandem with a Fe₂O₃ photoanode can achieve overall water splitting with an STH efficiency of 2.4%.^[74] Other photoanodes such as TiO₂, CdS, BiVO₄/WO₃, and BiVO₄/WO₃/SnO₂ have also been integrated with halide perovskite solar cells, as summarized in **Table 3**. In addition to photoanodes, photocathodes have also been used in tandem devices with halide perovskite PVs. Mayer group fabricated a tandem device using a Cu₂O as the photocathode and a FA_xMA_{1-x}PbI₃ solar cell connected to an IrO₂ as the anode.^[75] This device yield an STH of 2.5% for unbiased water splitting.

As summarized in **Table 3**, most halide perovskite solar cells incorporated into PV-PEC tandem devices are based on MAPbI₃ because of the material's relatively small bandgap (≈1.55 eV). However, one of the most important advantages of halide perovskites is their bandgap tunability (1.1–2.3 eV), which can lead to compatibility with a wide variety of photoelectrodes. Recently, cation (Cs⁺, FA⁺ and MA⁺) and anion (Br⁻ and I⁻) mixed halide perovskites have been demonstrated to have large open-circuit voltages and good stability, resulting in excellent tandem device performance when integrated with a Mo:BiVO₄ photoanode.^[76] In addition, Luo et al. fabricated a large-bandgap perovskite MAPbBr₃ (*E_g* = 2.3 eV) PV-photocathode tandem device, in which the photocathode was made of small-bandgap CuIn_xGa_{1-x}Se₂ (1.1 eV).^[77] Therefore, the halide perovskite solar cell was stacked on top of the photocathode. This tandem device yielded a high STH of ≈6%.

One of the key requirements of a PV-PEC tandem device is that the top layer with larger bandgap should be highly transparent. One way to meet this requirement when using an opaque photoanode(cathode) is to use a beam splitter to separate the solar spectrum into two light beams, which will be irradiated onto the photoanode(cathode) and solar cell separately.^[76,78] Another key issue is the significant energy loss due to the mismatch between the photocurrent of the wide-bandgap photoanode(cathode) and that of the narrow-bandgap solar cell (**Figure 10c**). Therefore, further improving the current of the photoanode(cathode) to make it compatible with that of the solar cell is crucial for improving the STH efficiency. To this end, the Sharp group has demonstrated a new three-terminal cell design in which a second junction is added to extract charge carriers that cannot be injected into the top junction due to current mismatch.^[79] This concept may be applied to halide perovskite PV-PEC tandem devices in the future.

Unlike the vastly reported study of water splitting, the study of CO₂ reduction using a PV-PEC tandem device is so far rarely reported. Jang et al. reported CO₂-to-CO conversion using a MAPbI₃ PV-ZnO@ZnTe@CdTe core-shell nanorod

Figure 10. a) Schematic diagram of a tandem MAPbI₃ PV–BiVO₄ device for solar-to-chemical fuel generation. b) Optical absorption and transmittance of the BiVO₄ thin film. Inset: photograph demonstrating the translucence and limited visible-light scattering of the spin-cast BiVO₄ thin film. c) Overlaid *J*–*V* characteristics of CoPi/BiVO₄ photoanode and MAPbI₃ solar cell. The photovoltaic parameters were recorded through a CoPi/BiVO₄ film. CoPi/BiVO₄ was measured in a three-electrode configuration with an Ag/AgCl reference electrode and a Pt counter electrode. The crossing point of the two curves designates the anticipated photocurrent output of the series-connected tandem device. d) Photocurrent density and calculated STH efficiency as a function of time for the MAPbI₃-CoPi/BiVO₄ device, demonstrating the ability to drive neutral water oxidation and reduction at 2.5% efficiency without external bias. array photocathode in tandem.^[80] With solar energy as the only energy source, this tandem device achieved a solar-to-CO conversion efficiency of 0.35%.

4.2. Photovoltaics Integrated with Electrocatalysis

Perovskite solar cells can serve as separate and external power sources to generate sufficient voltages to drive electrocatalysis. Grätzel and co-workers were first to demonstrate that two perovskite solar cells in tandem could power overall water splitting (Figure 11).^[8] Specifically, they used a MAPbI₃-based solar cell with a short-circuit photocurrent density (J_{sc}), open-circuit voltage (V_{oc}), fill factor and PCE of 21.3 mA cm^{-2} , 1.06 V, 0.76% and 17.3%, respectively. The electrocatalysts for both water reduction and oxidation were earth-abundant and robust NiFe layered double hydroxides (LDHs), which only required 1.7 V across the electrodes to achieve a 10 mA cm^{-2} water-splitting current in a 1 M NaOH aqueous electrolyte. Then, an overall water-splitting cell was assembled by connecting two MAPbI₃ solar cells (a tandem cell) to the NiFe LDH electrodes (Figure 11a,b). The tandem cell exhibited a J - V response with a V_{oc} of 2.00 V and a PCE of 15.7%, as depicted in Figure 11c. The authors predicted the operating current density of the integrated system (normalized to the total illuminated area of the solar cells) by defining the intersection of the J - V curves of the tandem cell and the catalyst electrodes in the two-electrode

configuration as the operating point. At this point, an operating current density of 10 mA cm^{-2} and STH of 12.3% can be obtained. This operating point of the water-splitting cell occurs very close to the maximum power point of the perovskite tandem cell (9.61 mA cm^{-2} at 1.63 V, PCE 15.7%), indicating that minimal energy is lost in converting electrical to chemical energy in this system. The authors further measured the current density in the standalone, unbiased light-driven configuration to confirm that the system indeed operated at 10 mA cm^{-2} with an STH of 12.3% (Figure 11d).

One of the drawbacks of this PV-electrocatalysis design is that the electrocatalyst for both water oxidation and water reduction in the same solution is very limited. In this regard, Grätzel and co-workers modified their electrocatalytic cell by separating the anode half-cell and cathode half-cell using a bipolar membrane.^[88] With this approach, the authors were able to expand the selection of a H₂ evolution catalyst in acid solution and an O₂ evolution catalyst in alkaline solution. Specifically, the authors selected CoP as the H₂ evolution catalyst in 0.5 M H₂SO₄ and NiFe LDH as the O₂ evolution catalyst in 1 M KOH. This cell only required 1.63 V to achieve a photocurrent density of 10 mA cm^{-2} . Thus, a high STH conversion efficiency of 12.7% was achieved upon the integration of the perovskite PV cell with this newly designed electrocatalytic cell.

The Grätzel group also applied this integrated PV-EC structure to reduce CO₂ to CO.^[89] Three MAPbI₃ solar cells were

connected in tandem to serve as a power source with a V_{oc} of 3.1 V, J_{sc} of 6.15 mA cm⁻² and PCE of 13.4%. Au and IrO₂ were selected as the electrocatalysts for CO₂ reduction and water oxidation at the cathode and anode ends, respectively. Powering this Au-IrO₂ electrocatalytic cell requires a driving voltage of at least 2 V, considering the thermodynamic voltage (CO₂ ⇌ CO + 1/2O₂; $\Delta E = 1.34$ V) and the overpotentials for the two electrodes (0.3 V on the cathode Au, 0.4 V on the anode IrO₂). The perovskite tandem cell was then integrated with the electrocatalytic cell to form a PV-electrocatalysis cell, operated at 5.8 mA cm⁻² for at least 18 h with a solar-to-CO efficiency exceeding 6.5%. This work represents a benchmark in sunlight-driven CO₂ conversion.

5. Conclusion and Future Prospects

While considerable effort has been devoted to studying different aspects of solar-to-chemical fuel conversions, the slow reaction rates, lack of efficient and stable materials, and the low energy density of sun light on the earth's surface (1 kW m⁻²), have hindered the development of solar-to-chemical fuel conversion approaches. Moreover, the complexity of the multicomponent photocatalysts and devices, and the nature of reaction media (aqueous environment) limit in-depth and/or in situ investigations of the materials using diffraction and electron spectroscopy-based techniques.

The recently discovered remarkable photophysical properties of halide perovskite semiconductors give hope for achieving practical solar-to-chemical fuel conversion approaches by utilizing those semiconductors. To date, various halide perovskite photocatalysts, photoelectrodes and reaction system configurations have been designed, studied, tested, and further improved. For instance, H₂ can be produced from HI using MAPbI₃ photocatalysts; photocatalytic CO₂ reduction can be achieved in ethyl acetate with CsPbBr₃ photocatalysts; and MAPbI₃ can be used as a photocathode or photoanode for reduction and oxidation reactions, respectively. Moreover, halide perovskite-based photovoltaics can be integrated with photoelectrocatalytic or electrocatalytic cells for bias-free water splitting or CO₂ reduction. Nevertheless, despite the efforts and achievements summarized above, halide perovskite materials are still in the early stages of exploration for solar-to-chemical fuel conversion systems. There is much room to enhance their stability, efficiency, and environmental friendliness for future practical applications. Below we mention several possible directions and associated challenges that are worthy of investigation in this area.

- 1) Functional perovskite@shell core-shell structures need to be further explored. A semiconducting or conducting shell will likely be needed to encapsulate a perovskite-core nanostructure for use in aqueous media. The shells could further facilitate charge carrier transfer via interfacial or band-alignment engineering across the core-shell structures. Functionalization of the shells with nanoparticles or ligands will enhance the efficiency of solar-to-chemical fuel conversion and enable a wide scope of photocatalytic applications (for example organic reactions^[90–92]) beyond water splitting and CO₂ reduction. However, construction of perovskite@shell structures

remains challenging, largely because halide perovskite materials are incompatible with the polar solvents that are typically used for shell formation reactions.

- 2) New protective layers or ligands should be developed for halide perovskites by exploring various coating and growth methodologies. Beyond merely the selection of new materials, coating halide perovskite photoelectrodes, or photovoltaics with a functional layer will require in-depth understanding of deposition approaches and their effect on the perovskite material. At present, most of the attention is paid to solution-based and evaporative growth methods for layers, while not enough attention is paid to hybrid, combination approaches and solid-to-melt approaches for coating design. Moreover, designing of the ligands that stabilized halide perovskite nanocrystals to be electron-donating or electron-withdrawing may also contribute to the reduction or oxidation reactions.
- 3) Additional attention should be directed to halide perovskite nanostructures. The effect of surface reactivity on the catalytic properties and phase stability of halide perovskite nanostructures becomes significant because of their large surface-area-to-volume ratios. Nanostructure design could fundamentally help in understanding structure-sensitive properties and the dynamics between surface and bulk, which will promote the discovery of active and stable catalysts with enriched surface-active sites.
- 4) The design of reaction solution systems and tandem device configurations need further optimization. Reaction systems of various viable solutions should be explored for halide perovskites in conjunction with targeting reactions beyond water splitting or CO₂ reduction. As for tandem device configurations, issues such as electrical current mismatch, opaque top layers, and large series resistance need to be solved.
- 5) Attention should be paid to the development of lead-free halide perovskites. Most of the present high-performance photocatalysts and devices are based on lead halide perovskites; however, the toxicity of lead creates serious environmental concerns. To this end, tin-based and double halide perovskites^[93] with comparable photophysical properties could be explored as alternatives. In summary, tremendous efforts have been made to enable halide perovskites to be useful for solar-to-chemical fuel conversion. In this review, we have summarized and discussed strategies established for fabricating halide perovskites for utilization in photocatalytic particle-suspension systems, photoelectrode thin-film systems, and photovoltaic-(photo)electrocatalytic tandem systems that target water splitting, HI splitting, and CO₂ reduction reactions. The future of halide perovskites in those applications is promising but will depend on discovering new and stable perovskite materials, developing protective and functional shells and layers, and designing suitable reaction solution systems as well as optimized tandem device configurations.
