This is a PDF file of an unedited manuscript that has been accepted for publication. As a service to our customers we are providing this early version of the manuscript. The manuscript will undergo copyediting, typesetting, and review of the resulting proof before it is published in its final form. Please note that during the production process errors may be discovered which could affect the content, and all legal disclaimers that apply to the journal pertain.
RESEARCH HIGHLIGHTS:

- The paper provides expressions for quadrature rules on the space of $C^1$ cubic splines with non-uniform, symmetrically stretched knot sequences.
- Any function from the space is exactly integrated by the rule.
- The quadrature nodes and weights are derived via explicit recursion formulae, with no intervention of any numerical solver.
- The rule is optimal, i.e. it requires minimal number of nodes.
Explicit Gaussian quadrature rules for $C^1$ cubic splines with symmetrically stretched knot sequences

Abstract

We provide explicit expressions for quadrature rules on the space of $C^1$ cubic splines with non-uniform, symmetrically stretched knot sequences. The quadrature nodes and weights are derived via an explicit recursion that avoids an intervention of any numerical solver and the rule is optimal, that is, it requires minimal number of nodes. Numerical experiments validating the theoretical results and the error estimates of the quadrature rules are also presented.

Keywords: Gaussian quadrature, cubic splines, Peano kernel, B-splines

1. Introduction

The problem of numerical quadrature has been of interest for decades due to its wide applicability in many fields spanning collocation methods [22], integral equations [1], finite elements methods [23] and most recently, isogeometric analysis [6]. Moreover, despite finite volume methods typically do not employ quadrature rules, recent high-order finite volume methods such as those based on the semi-Lagrangian formulation started using numerical quadrature as an essential element [26]. Computationally, the integration of a function is an expensive procedure and quadrature turned out to be a cheap, robust and elegant alternative.

A quadrature rule, or shortly a quadrature, is said to be an $m$-point rule, if $m$ evaluations of a function $f$ are needed to approximate its weighted integral over an interval $[a, b]$

$$\int_a^b \omega(x)f(x)\,dx = \sum_{i=1}^{m} \omega_i f(\tau_i) + R_m(f),$$

(1)
where $\omega$ is a fixed non-negative weight function defined over $[a, b]$. Typically, the rule is required to be exact, that is, $R_m(f) \equiv 0$ for each element of a predefined linear function space $L$. In the case when $L$ is the linear space of polynomials of degree at most $2m - 1$, then the $m$-point Gaussian quadrature rule [9] provides the optimal rule that is exact for each element of $L$, i.e. $m$ is the minimal number of nodes $\tau_i$ at which $f$ has to be evaluated. The Gaussian nodes are the roots of the orthogonal polynomial $\pi_m$ where $(\pi_0, \pi_1, \ldots, \pi_m, \ldots)$ is the sequence of orthogonal polynomials with respect to the measure $\mu(x) = \omega(x)dx$. Typically, the nodes of the Gaussian quadrature rule are computed numerically using for example, the Golub-Welsh algorithm [10], in the case the three-term recurrence relations for the orthogonal polynomials can be expressed.

In the case when $L$ is a Chebyshev space of dimension $2m$, Studden and Karlin proved the existence and uniqueness of optimal $m$-point generalized quadrature rules, which due to optimality are also called Gaussian, that are exact for each element of the space $L$ [12]. The nodes and weights of the quadrature rule can be computed using numerical schemes based on Newton methods [15].

In the case when $L$ is a linear space of splines, a favourite alternative to polynomials due to their approximation superiority and the inherent locality property [5, 7, 8], Micchelli and Pinkus [16] derived the optimal number of quadrature nodes. Moreover, the range of intervals, the knot sequence subintervals that contain at least one node, was specified. Their formula preserves the “double precision” of Gaussian rules for polynomials, that is, for a spline function with $r$ (simple) knots, asymptotically, the number of nodes is $[5]$. The computation of the nodes and weights of the optimal spline quadrature (Gaussian quadrature) is rather a challenging problem as the non-linear systems the nodes and weights satisfy depend on truncated power functions. The systems become algebraic only with the right guess of the knot intervals where the nodes lie.

In the literature, the term optimality may also refer to the approximation error that the quadrature rule produces. That is, the number of nodes is given and their layout is sought such that it minimizes the error for a given class of functions. Köhler and Nikolov [13, 14] showed that the Gauss-type quadrature formulae associated with spaces of spline functions with equidistant knots are asymptotically optimal in the non-periodic Sobolev classes. This is a motivation for studying Gauss-type quadrature formulae for spaces of spline functions, in particular, with equidistant knots. In this paper, by optimal we exclusively mean quadrature rules with the minimal number of nodes.

Regarding the optimal quadrature rules for splines, the quadrature schemes differ depending on the mutual relation between the degree and continuity $(d, c)$. For cases with lower continuity, a higher number of nodes is required for the optimal quadrature rule. Also, the choice of the domain can bring a significant simplification. In the case when the domain is the whole real line, an exact and optimal rule is obtained by only evaluating $f$ at every second knot (midpoint) for uniform splines of even (odd) degree [11]. For a closed interval, however, the rule is no longer exact for a general $f$ and the problem can be resolved only by adding additional nodes and employing numerical solvers [2]. The rule becomes
exact but is not optimal.

Thus, the insightful proposition of Nikolov [19], which yield optimal and explicit quadrature rules for (3, 1) uniform splines (with $\omega = 1$), is surprising. In Nikolov’s scheme, a recursive relation between the neighboring nodes is derived and, since the resulting system is of cubical degree, a closed form formula is given to iteratively compute the nodes and weights. Recently, the optimal rules for quadratic splines with uniform knots has been derived in [20].

In this paper, we generalize the quadrature rules of [19] for splines with certain non-uniform knot sequences, keeping the desired properties of explicitness, exactness and optimality. The rest of the paper is organized as follows. In Section 2, we recall some basic properties of (3, 1) splines and derive their Gaussian quadrature rules. In Section 3, the error estimates are given and Section 4 shows the numerical experiments. Finally, possible extensions of our method are discussed in Section 5.

2. Gaussian quadrature formulae for $C^1$ cubic splines

In this section we recall a few basic properties of (3, 1) splines and derive explicit formulae for computing quadrature nodes and weights for a particular family of knot sequences. Throughout the paper, $\pi_n$ denotes the linear space of polynomials of degree at most $n$ and $[a, b]$ is a non-trivial real compact interval.

2.1. $C^1$ cubic splines with symmetrically stretched knot sequences

We start with the definition of the particular knot sequences above which the spline spaces are built.

**Definition 2.1.** A finite sequence $X_n = (a = x_0, x_1, ..., x_{n-1}, x_n = b)$ of pair-wise distinct real numbers in the interval $[a, b]$ is said to be a symmetrically stretched knot sequence if the sequence is symmetric with respect to the midpoint of the interval $[a, b]$ and such that

$$x_k - 2x_{k+1} + x_{k+2} \geq 0 \quad \text{for} \quad k = 0, ..., \lfloor \frac{n}{2} \rfloor - 1,$$

where $\lfloor \cdot \rfloor$ is the floor function.

Denote by $S_{n, 1}^3$ the linear space of $C^1$ cubic splines over a symmetrically stretched knot sequence $X_n = (a = x_0, x_1, ..., x_n = b)$

$$S_{n, 1}^3 = \{ f \in C^1[a, b] : f|_{(x_k, x_{k+1})} \in \pi_3, k = 0, ..., n - 1 \}.$$  \hspace{1cm} (3)

The dimension of the space $S_{n, 1}^3$ is $2n + 2$.

**Remark 1.** In the B-spline literature [5, 7, 8], the knot sequence is usually written with knots’ multiplicities. As in this paper the multiplicity is always two at every knot, we omit the classical notation and, throughout the paper, write $X_n$ without multiplicity, i.e. $x_k < x_{k+1}$, $k = 0, \ldots, n - 1$.
Similarly to [19], we find it convenient to work with the non-normalized B-spline basis. To define the basis, we extend our knot sequence $X_n$ with two extra knots outside the interval $[a,b]$ that we set to be $x_{-1} = 2x_0 - x_1$ and $x_{n+1} = 2x_n - x_{n-1}$.

Note that the choice of $x_{-1}$ and $x_{n+1}$ is to get particular integrals in (6) that simplify expressions in Section 2.2. We emphasize that this setting does not affect the quadrature rule derived later in Theorem 2.1. Denote by $D = \{D_i\}_{i=1}^{2n+2}$ the basis of $S_n^{a,b}$ where

$$D_{2k-1}(t) = [x_{k-2}, x_{k-2}, x_{k-1}, x_k](t - t_+)^3,$$

$$D_{2k}(t) = [x_{k-2}, x_{k-1}, x_{k-1}, x_k](t - t_+)^3,$$

where $[.]f$ stands for the divided difference and $u_+ = \max(u, 0)$ is the truncated power function, see Fig. 1. Among the basic properties of the basis $D$, we need to recall the fact that for any $k = 1,2,\ldots,n+1$, $D_{2k-1}$ and $D_{2k}$ have the same support, that is, $\text{supp}(D_{2k-1}) = \text{supp}(D_{2k}) = [x_{k-2}, x_k]$, and $D_{2k-1}(t) > 0$, $D_{2k}(t) > 0$ for all $t \in (x_{k-2} - x_k)$. Moreover, for $k = 3,\ldots,2n$, we have

$$I[D_k] = \frac{1}{4} \quad \text{for} \quad k = 3,4,\ldots,2n,$$

where $I[f]$ stands for the integral of $f$ over the interval $[a,b]$. We work with non-normalized basis functions, and therefore the integrals above are independent on the knot sequence. The computation of integrals (5) can be found, e.g., in [8]. With the choice made in (4), a direct integration gives

$$I[D_1] = I[D_{2n+2}] = \frac{1}{16} \quad \text{and} \quad I[D_2] = I[D_{2n+1}] = \frac{3}{16}.$$
Using the standard definition of divided difference for multiple knots, explicit expressions for $D_{2k-1}(t)$ and $D_{2k}(t)$ with $t \in [x_{k-2}, x_k]$ are obtained as

$$D_{2k-1}(t) = a_k(x_k - t)^3_+ + b_k(x_{k-1} - t)^3_+ + c_k(x_k - t)^2_+,$$

(7)

where, setting $h_k = x_k - x_{k-1}$ for $k = 0, 1, \ldots, n + 1$,

$$a_k = \frac{1}{h_k^2(h_k + h_{k-1})^2}, \quad b_k = \frac{2h_k - h_{k-1}}{h_{k-1}h_k^2}, \quad c_k = \frac{-3}{h_{k-1}h_k^2}.$$

Similarly, we obtain

$$D_{2k}(t) = \alpha_k(x_k - t)^3_+ + \beta_k(x_k - t)^2_+ + \gamma_k(x_{k-1} - t)^2_+ + \eta_k(x_k - t)^2_+,$$

(8)

where

$$\alpha_k = \frac{-3h_k - 2h_{k-1}}{(h_k + h_{k-1})^2h_k^2}, \quad \beta_k = \frac{3}{(h_k + h_{k-1})h_k^2}, \quad \gamma_k = \frac{2h_k - h_{k-1}}{h_{k-1}h_k^2}, \quad \eta_k = \frac{3}{h_{k-1}h_k^2}.$$

That is, $D_{2k-1}$ and $D_{2k}$ are expressed by three parameters $x_{k-2}$, $x_{k-1}$ and $x_k$, due to the fact that $[x_{k-2}, x_k]$ is the maximal interval where both have a non-zero support, see Fig. 1. Moreover, we have the following:

**Lemma 2.1**. Let $X_n = (a = x_0, x_1, \ldots, x_n = b)$ be a symmetrically stretched knot sequence. Then for any $k = 2, \ldots, [n/2] + 1$

$$D_{2k-1}(t) > D_{2k}(t) \quad \text{for any} \quad t \in (x_{k-2}, x_{k-1}).$$

**Proof**. Over the interval $(x_{k-2}, x_{k-1})$, the function $Q = D_{2k-1} - D_{2k}$ is a single cubic polynomial. Therefore, it can be expressed in terms of Bernstein basis
and can be viewed as a Bézier curve on \((x_{k-2}, x_{k-1})\), see Fig. 2,
\[ Q(t) = \sum_{i=0}^{3} q_i B_3^i(t), \quad \text{where} \quad B_3^i(t) = \binom{3}{i} \left( \frac{t-x_{k-2}}{x_{k-1}-x_{k-2}} \right)^i \left( \frac{x_{k-1}-t}{x_{k-1}-x_{k-2}} \right)^{3-i}. \]

Using the conversion between the monomial and Bernstein bases, see e.g., [8], the control points \((q_0, q_1, q_2, q_3)\) of \(Q\) over the interval \([x_{k-2}, x_{k-1}]\) are derived as
\[ (q_0, q_1, q_2, q_3) = \left( 0, 0, \frac{1}{x_k - x_{k-2}}, \frac{x_k - 2x_{k-1} + x_{k-2}}{(x_k - x_{k-2})^2} \right). \]

Therefore, according to (2), the control points are nonnegative, with the third control point \(q_2\) strictly positive. Therefore, \(Q\) can only vanish at \(x_{k-2}\) and \(x_{k-1}\) and is strictly positive over \((x_{k-2}, x_{k-1})\).

### 2.2. Gaussian quadrature formulae

In this section, we derive a quadrature rule for the family \(S_{n,1}^n\), see (3), and show it meets the three desired criteria, that is, the rule is optimal, exact and explicit. With respect to exactness, according to [16, 17] there exists a quadrature rule
\[ Q_n^b[f] = \int_a^b f(t) dt = \sum_{i=1}^{n+1} \omega_i f(\tau_i) \quad (9) \]
that is exact for every function \(f\) from the space \(S_{n,1}^n\). The explicitness and optimality follow from the construction.

**Lemma 2.2.** Let \(X_n = (a = x_0, x_1, \ldots, x_n = b)\) be a symmetrically stretched knot sequence. Each of the intervals \(J_k = (x_{k-1}, x_k) (k = 1, \ldots, \lfloor n/2 \rfloor)\) contains at least one node of the Gaussian quadrature rule (9).

**Proof.** We proceed by induction on the index of the segment \(J_k\). There must be a node of the Gaussian quadrature rule in the interval \(J_1\), otherwise, using the exactness of the quadrature rule for \(D_1\), we obtain \(I[D_1] = 0\) which contradicts equalities (6). Now, let us assume that every segment \(J_l\) contains – one or several – Gaussian nodes for \(l = 1, 2, \ldots, k - 1\). If the interval \(J_k\) has no Gaussian nodes, then using Lemma 2.1, we arrive to the following contradiction
\[ \frac{1}{4} = I[D_{2k}] = \sum_{\tau_j \in J_{k-1}} \omega_j D_{2k}(\tau_j) < \sum_{\tau_j \in J_{k-1}} \omega_j D_{2k+1}(\tau_j) = I[D_{2k+1}] = \frac{1}{4}. \]

**Corollary 1.** If \(n\) is an even integer, then each of the intervals \(J_k = (x_{k-1}, x_k) (k = 1, 2, \ldots, n)\) contains exactly one Gaussian node and the middle \(x_{n/2} = (a + b)/2\) of the interval \([a, b]\) is also a Gaussian node. If \(n\) is odd then each of the intervals \(J_k = (x_{k-1}, x_k) (k = 1, 2, \ldots, n; k \neq (n + 1)/2)\) contains exactly one Gaussian node, while the interval \(J_{(n+1)/2}\) contains two Gaussian nodes, positioned symmetrically with respect to \((a + b)/2\).
Proof. If \( n \) is an even number then by symmetry, we obtain at least one Gaussian node in each interval \( J_k \) for \( k = 1, 2, \ldots, n \). If one of the intervals \( J_k \) has more than one node then by symmetry, we get more than \( n + 2 \) nodes for the quadrature, contradicting our quadrature rule (9). Moreover, by virtue of symmetry, the last missing Gaussian node is forced to be the middle of the interval. Now, if \( n \) is an odd integer, then by symmetry, each of the intervals \( J_k, k = 1, 2, \ldots, n \) contains at least one Gaussian node. Let us assume that the middle interval \( J_{(n+1)/2} \) contains exactly one node, then at least one of the remaining intervals contains two nodes. By symmetry, the number of nodes will be at least \( (n + 2) \), contradicting our quadrature rule (9). Therefore, the middle interval \( J_{(n+1)/2} \) contains exactly two nodes while each of the remaining intervals contain exactly one Gaussian node of the quadrature rule (9). \( \square \)

Throughout the rest of this work, we use the following notation: For \( k = 1, 2, \ldots, \lfloor n/2 \rfloor + 1 \), we set

\[
\theta_k = x_k - \tau_k; \quad \rho_k = x_{k+1} - \tau_k \quad \text{and} \quad \omega_k = (a_{k+1} \rho_k^3 + b_{k+1} \theta_k^2 + c_{k+1} \theta_k^3) \quad \text{(10)}
\]

Inserting the Gaussian node \( \tau_k \) into the explicit representations (7) and (8) of the spline bases gives

\[
\begin{align*}
D_{2k-1}(\tau_k) &= \alpha_k \theta_k^3, \\
D_{2k}(\tau_k) &= \alpha_k \theta_k^3 + \beta_k \theta_k^2, \\
D_{2k+1}(\tau_k) &= \alpha_k \theta_k^3 + b_{k+1} \theta_k^2 + c_{k+1} \theta_k^3, \\
D_{2k+2}(\tau_k) &= \alpha_k \theta_k^3 + b_{k+1} \theta_k^2 + c_{k+1} \theta_k^3 + \eta_{k+1} \theta_k^2. 
\end{align*}
\]

We are ready now to proceed with the recursive algorithm which starts at the domain’s first subinterval \([x_0, x_1]\) by computing the first node and weight, and sequentially parses the subintervals towards the domain’s midpoint, giving explicit formulae for the remaining unknowns \( \tau_i, \omega_i, i = 2, \ldots, \lfloor n/2 \rfloor + 1 \). There is, according to Corollary 1, a unique Gaussian node in the interval \([x_0, x_1]\). This node is obtained by solving the system

\[
\begin{align*}
\frac{1}{16} &= I[D_1] = Q_{x_1}^{x_0}[D_1] = \omega_1 D_1(\tau_1) = \omega_1 \alpha_1 \theta_1^3, \\
\frac{3}{16} &= I[D_2] = Q_{x_1}^{x_0}[D_2] = \omega_1 D_2(\tau_1) = \omega_1 (\alpha_1 \theta_1^3 + \beta_1 \theta_1^2),
\end{align*}
\]

leading to the unique solution for \( \theta_1 \) and \( \omega_1 \) to be expressed as

\[
\theta_1 = \frac{\beta_1}{3a_1 - \alpha_1} = \frac{3}{4} h_1 \quad \text{and} \quad \omega_1 = \frac{1}{16a_1 \theta_1^3} = \frac{16}{27} h_1.
\]

The remaining nodes and weights are computed in turn explicitly using the recipe formalized as follows:
Theorem 2.1. The sequence of nodes and weights of the Gaussian quadrature rule (9) are given explicitly as
\[ \theta_1 = \frac{3}{4} h_1, \omega_1 = \frac{16}{27} h_1 \] and for \( i = 1, 2, \ldots, [n/2] - 1 \) by the recurrence relations
\[ \theta_{i+1} = \frac{A_i \beta_{i+1}}{a_{i+1} B_i - a_i A_i}, \quad \omega_{i+1} = \frac{A_i}{a_{i+1} \theta_{i+1}}. \quad (12) \]
If \( n \) is even (\( n = 2m \)) then \( \tau_{m+1} = x_m = (a + b)/2 \) and
\[ \omega_{m+1} = \frac{A_m + B_m - \frac{1}{4}}{a_{m+1} \theta_{m+1}^3}. \quad (13) \]
If \( n \) is odd (\( n = 2m - 1 \)) then \( \theta_m \) is the greater root in \((0, x_m - x_{m-1})\) of the cubic equation
\[ (A_{m-1}(\alpha_m + b_{m+1}) - B_{m-1}(a_m + c_{m+1})) \theta_m^3 + (A_{m-1} \beta_m + c_{m+1}) \theta_m^2 + (A_{m-1} a_{m+1} - B_{m-1} \alpha_m) \rho_m^3 - B_{m-1} \beta_{m+1} \rho_m^2 = 0, \]
and
\[ \omega_m = \left(\frac{\gamma_m + a_m}{\theta_m^3} + \eta_m \theta_m^2 + \alpha_m + \beta_m \rho_m^3 + \beta_{m+1} \rho_m^2\right)^{m-1}. \]

Proof. The proof proceeds by induction. We assume \( \theta_i, \omega_i \) known for \( i = 1, 2, \ldots, k \) (\( k \leq [n/2] - 2 \)). Using (11) we compute \( \theta_{k+1} \) and \( \omega_{k+1} \) by solving the system \( Q_{x_k+1}^k [D_{2k+1}] = 1/4 \) and \( Q_{x_k+1}^{k+1} [D_{2k+2}] = 1/4 \), that is
\[ \frac{1}{4} = \omega_k D_{2k+1}(\tau_k) + \omega_{k+1} D_{2k+1}(\tau_{k+1}) = \left(\frac{1}{4} - A_k\right) + \omega_{k+1} a_k \theta_k^{3k+1}; \]
\[ \frac{1}{4} = \omega_k D_{2k+2}(\tau_k) + \omega_{k+1} D_{2k+2}(\tau_{k+1}) = \left(\frac{1}{4} - B_k\right) + \omega_{k+1} (\alpha_k + \beta_k + \rho_k^{3k+1}). \]
Eliminating \( \omega_{k+1} \) leads to the recurrence relations (12). If \( n \) is even (\( n = 2m \)), then by Corollary 1 we have \( \tau_{m+1} = (a + b)/2 \). To compute the associated weight \( \omega_{m+1} \), we take into account the symmetry, which gives \( \omega_m = \omega_{m+2} \) and
\[ D_{2m+1}(\tau_{m+2}) = D_{2m+2}(\tau_m); \]
and solve
\[ \frac{1}{4} = Q_{x_m}^{m+1} [D_{2m+1}] = \omega_m D_{2m+1}(\tau_m) + D_{2m+2}(\tau_m) = \omega_{m+1} D_{2m+1}(\tau_{m+1}). \]

Using (11), we obtain (13). If \( n \) is odd (\( n = 2m - 1 \)), then according to Corollary 1 the two nodes \( \tau_m \) and \( \tau_{m+1} \) belong to the interval \((x_m - x_{m-1}, x_m)\). Due to the symmetry, we have \( \omega_m = \omega_{m+1} \) and \( \tau_{m+1} = (a + b) - \tau_m \) and
\[ D_{2m+1}(\tau_{m+1}) = D_{2m+2}(\tau_m), \quad D_{2m}(\tau_{m+1}) = D_{2m-1}(\tau_{m}). \]
Using the exactness of the quadrature rule for \( D_{2m-1} \) and \( D_{2m} \), we obtain
\[ \omega_m a_m \theta_m^3 = A_{m-1} + B_m - \frac{1}{4} \]
\[ \omega_m (\alpha_m \theta_m^3 + \beta_m \theta_m^2) = A_m + B_{m-1} - \frac{1}{4} \]
Solving the above system for \( \theta_m \) and \( \omega_m \) proves the theorem. \( \square \)
3. Error estimation for the \( C^1 \) cubic splines quadrature rule

In the previous section, we have derived a quadrature rule that exactly integrates functions from \( S_{3,1}^n \). If \( f \) is not an element of \( S_{3,1}^n \), the rule produces a certain error, also called remainder, and the analysis of this error is the objective of this section.

Let \( W_1^r = \{ f \in C^{r-1}[a,b]; \, f^{(r-1)} \text{abs. cont.}, \, ||f^{(r)}||_{L_1} < \infty \} \). As the quadrature rule (9) is exact for polynomials of degree at most three, for any element \( f \in W_1^d \), \( d \geq 4 \), we have

\[
R_{n+1}[f] := I[f] - Q_{n+1}[f] = \int_a^b K_4(R_{n+1}; t)f^{(4)}(t)dt,
\]

where the Peano kernel [9] is given by

\[
K_4(R_{n+1}; t) = R_{n+1} \left[ \frac{(t - \cdot)^3}{3!} \right].
\]

An explicit representation for the Peano kernel over the interval \([a,b] \) in terms of the weights and nodes of the quadrature rule (9) is given by

\[
K_4(R_{n+1}; t) = \frac{(t - a)^4}{24} - \frac{1}{6} \sum_{k=1}^{n+1} \omega_k (t - \tau_k)^3.
\] (14)

Moreover, according to a general result for monosplines and quadrature rules [16], the only zeros of the Peano kernel over \([a, b] \) are the double knots of the cubic spline, see Section 4 in particular Fig. 5 for an illustration. Therefore, for any \( t \in (a,b) \), \( K_4(R_{n+1}; t) \geq 0 \) and, by the mean value theorem for integration, there exists a real number \( \xi \in [a,b] \) such that for \( f \in C^4[a,b] \)

\[
R_{n+1}(f) = c_{n+1,4}f^{(4)}(\xi) \quad \text{with} \quad c_{n+1,4} = \int_a^b K_4(R_{n+1}; t)dt. \quad (15)
\]

Hence, the constant \( c_{n+1,4} \) of the remainder \( R_{n+1} \) is always positive and our quadrature rule belongs to the family of positive definite quadratures of order 4, e.g., see [18, 19, 21]. Integration of (14) yields the following result.

**Theorem 3.1.** The error constant \( c_{n+1,4} \) in (15) is given by

\[
c_{n+1,4} = \frac{(b-a)^5}{120} - \frac{1}{24} \sum_{k=1}^{n+1} \omega_k (b - \tau_k)^4. \quad (16)
\]

**Remark 2.** To compute an alternative expression of the constant \( c_{n+1,4} \), we can follow the approach of [19] by using the exactness of our quadrature rule for the truncated powers \((x_k - t)^3, (x_k - t)^3; k = 0, 1, \ldots, n \). As the symmetrically stretched knot sequences satisfy the assumptions of Theorem 2.2 in [19],

9
the proof applies literally to our non-uniform setting, and the constant of the
remainder is expressed as:

\[
c_{n+1,4} = \frac{1}{720} \sum_{k=0}^{[(n+1)/2]} (x_{k+1} - x_k)^5 - \frac{1}{12} \sum_{k=1}^{[(n+1)/2]} \omega_k (x_{k-1} - \tau_k)^2 (x_k - \tau_k)^2. \tag{17}
\]

4. Numerical Experiments

We applied the quadrature rule to various symmetrically stretched knot se-
quences; the nodes and weights computed by our formulae are summarized in
Table 1. Even though the space of admissible stretched knot sequences is infinite
dimensional, for the sake of simplicity, the proposed quadrature rule was tested on
those that are determined by the fewest possible number of parameters.

One such a prominent symmetrically stretched knot sequence stems from
Chebyshev polynomials [9], where its degree \( N \) determines the roots which can
be written as

\[
x_k = -\cos(\phi_k), \quad \phi_k = \frac{2k-1}{2N} \pi, \quad k = 1, 2, \ldots, N \quad \tag{18}
\]
Table 1: Nodes and weights for particular knot sequences. N denotes the number of internal knots. All the knots and weights are normalized on unit interval and, due to the symmetry, only first \( \lfloor \frac{N}{2} \rfloor + 2 \) nodes and weights are shown.

and the roots, according to Def. 2.1, obviously form a non-uniform, symmetrically stretched knot sequence on \([-1, 1]\). The corresponding nodes and weights for \( n - 1 = N = 5 \) are shown in Fig. 3. Similarly, Legendre polynomials \([24]\) satisfy the requirement that their roots form a symmetrically stretched sequence. In order to have a qualitative comparison of the weights for Chebyshev and Legendre knot sequences, and also for the comparison of their Peano kernels, see Fig. 5, the roots of Chebyshev polynomial were mapped to the unit domain.

Another family of symmetrically stretched knot sequences are those where the lengths of two neighboring knots form a geometric sequence, i.e. the stretch...
Figure 4: For geometric knot sequences, the length of neighboring subintervals growth geometrically, i.e. $x_{k+1} - x_k = q(x_k - x_{k-1})$. The basis functions for a fixed number of internal knots ($N = 5$) with various $q$ are shown. The green dots interpret the quadrature rule; their $x$-coordinates are the nodes and the $y$-coordinates are the weights.

The stretching ratio $q$ is constant, see Fig. 4. Obviously, the quadrature rule of Nikolov [19] is a special case for $q = 1$. In some applications such as solving the 1D heat equation [25] or simulating turbulent flows in 3D [3, 4], where the finer and finer subdivisions closer to the domain boundary are needed, the uniform rule would eventually require large number of knots whilst setting a proper non-uniform knot sequence could reduce the number of evaluations significantly. The Peano kernels of geometric knot sequences considered as a function of the stretching ratio $q$ are shown in Fig. 6. It is not surprising, rather an expected result that the error constant $c_{n+1,4}$ looks favorably for the uniform knot sequence as the uniform layout is a certain equilibrium, that is, a minimizer of the first term on the left side in (17).

We emphasize that these three types of non-uniform knot sequences are particular examples, one can use any knot sequence satisfying Def. 2.1 that is suitable for a concrete application. In all the numerical examples shown in the paper, we observed a similar phenomenon as in [19], namely that the weights are monotonically increasing when coming from the side to the middle of the interval, see Table 1. However, the proof for non-uniform knot sequences turned out to be rather difficult and we content ourselves here to formulate it as an open problem, namely the quadrature nodes and weights computed in Theorem 2.1,
Figure 5: Peano kernels representing the constant $c_{n+1,4}$, see Eq. (15), for Chebyshev and Legendre knot sequences for $N = 5$ and $7$ internal knots on the unit domain are shown.

Figure 6: Peano kernels of a geometric knot sequence with $N = 5$ and $7$ internal knots as a function of the scaling ratio $q$ are shown. The cut by $q = \text{const.}$ plane is the corresponding univariate Peano kernel on $[0, 1]$ and its integral represents the error constant $c_{n+1,4}$, see (15). The front boundary curve ($q = 1$) is the Peano kernel associated with the uniform knot sequence.

satisfy the inequalities

$$\omega_i < \theta_i < \omega_{i+1} \quad \text{for} \quad i = 1, \ldots, \left\lfloor \frac{n}{2} \right\rfloor.$$
5. Conclusion and future work

We have derived a quadrature rule for spaces of $C^1$ cubic splines with symmetrically stretched knot sequences. The rule possesses three crucial properties: we can exactly integrate the functions from the space of interest; the rule requires minimal number of evaluations; and the rule is defined in closed form, that is, we give explicit formulae without need of any numerical algorithm. To the best knowledge of the authors, the result is the first of the kind that handles non-uniform knot sequences explicitly and, even though the symmetrical stretching seems to be relatively restrictive, we believe that the infinite dimensional space of possible knot sequences where the rule applies makes it a useful tool in many engineering applications.

Moreover, our quadrature rule is still exact, even though not optimal, for $C^2$ cubic splines. Due to its explicitness, it can also be freely used in various applications instead of $(3,2)$ splines quadrature rules, for which the explicit formulae are not known. In the future, we intent to derive quadrature rules for other spline spaces, while aiming at particular engineering application.
