Abstract

The prototypical system for understanding doping in solution-processed organic electronics has been poly(3-hexylthiophene) (P3HT) p-doped with 2,3,5,6-tetrafluoro-7,7,8,8-tetracyanoquinodimethane (F₄TCNQ). Multiple charge transfer states, defined by the fraction of electron transfer to F₄TCNQ, are known to coexist and are dependent on polymer molecular weight, crystallinity, and processing. Less well understood is the loss of conductivity after thermal annealing of these materials. Specifically, in thermoelectrics, F₄TCNQ-doped regioregular (rr) P3HT exhibits significant conductivity losses at temperatures lower than other thiophene-based polymers. Through detailed spectroscopic investigation of progressively heated P3HT films co-processed with F₄TCNQ, we demonstrate that this diminished conductivity is due to formation of the non-chromophoric, weak dopant HF₄TCNQ⁻. This species is likely formed through hydrogen abstraction from the alpha aliphatic carbon of the hexyl chain at the 3-position of thiophene rings of rr-P3HT. This reaction is eliminated for polymers with ethylene glycol-containing side chains, which retain conductivity at higher operating temperatures. In total, these results provide a critical materials design guideline for organic electronics.

Molecularly-doped organic semiconductors are of interest for use in organic electronic devices including thermoelectrics,¹⁻⁴ light emitting diodes,⁵ photovoltaics,⁶⁻¹⁰ and field effect transistors.¹¹⁻¹⁵ Although organic electronics are experiencing an increased presence in the market, critical challenges remain for long-term use of these materials, including low conductivity and chemical stability. Increased conductivity is typically achieved by doping with p- or n-type species that generate mobile free charge carriers from intermolecular electron transfer reactions between the matrix and dopant.¹⁶ External operational factors such as light exposure and heat can accelerate chemical instability of active layers and negatively impact functional lifetime. This instability can be manifested in multiple ways, including undesired side reactions leading to the formation of degradation products and/or morphological changes in matrix microstructure. This work focuses on understanding thermal stability in the model system of 2,3,5,6-tetrafluoro-7,7,8,8-tetracyanoquinodimethane (F₄TCNQ)-doped regioregular poly(3-hexylthiophene) (rr-P3HT) and the implications of this thermal stability for conductivity of the active layer.

Early reports on this well-studied system focused on the elucidation of key structure-property relationships. Doping efficiency (as indicated by conductivity) was shown to be dependent on dopant concentration in co-processed films and was attributed to the presence of dopants only in amorphous domains of rr-P3HT at low concentrations with intercalation into crystalline domains at higher concentrations.¹⁷ It was later found that use of a sequential processing method provides improved doping efficiency due to better doping predictability and the ability to direct the dopant to crystalline or amorphous regions of the polymer by choice of solvent and post-doping film processing.¹⁶ Méndez et al. provided an energy description of the doping process that identified two possible doping pathways: integer charge transfer (ICT) resulting from full electron donation from the rr-P3HT to F₄TCNQ, or formation of a partial charge transfer complex (CPX)

1
2
3 due to hybridization of dopant and host molecular orbitals.¹⁸⁻¹⁹ The co-existence of these two
4 charge transfer states in F₄TCNQ-doped rr- and regiorandom (rra)-P3HT thin films has recently
5
6 been reported from these laboratories, with the relative amounts of each being generally correlated
7
8 with P3HT matrix microstructure.²⁰
9
10

11
12 Despite significant advancements in understanding this system, chemical and thermal
13 stability of the relevant doped states necessary for longevity in functional properties have generally
14
15 been overlooked in prior studies. We have shown that although the ICT state appears to be
16
17 kinetically favored, the more thermodynamically stable of these states is the CPX state in co-
18
19 processed films, serving as charge trap sites that reduce conductivity.²¹ However, there is a dearth
20
21 of information about the relative thermal stability of these two states. Past work has suggested the
22
23 contributions of three possible factors to explain the thermal instability of small molecule doped
24
25 polymer active layers: 1) chemical reaction of molecules in the active layer upon exposure to
26
27 thermal stress;²² 2) change in or disappearance of charge transfer states;^{21, 23} and 3) the physical
28
29 loss and/or migration of dopant.^{16, 24-26} All three processes have important implications for
30
31 efficiency of the active layer, and one or more of these processes may be inter-related.
32
33
34
35
36

37
38 The stability of pure rr-P3HT to thermal stress has been well characterized,²² but recent
39
40 efforts to characterize the stability of F₄TCNQ in F₄TCNQ-doped polymer blends have resulted in
41
42 contradictory results, particularly at moderate temperatures between 80 and 120 °C.^{24-25, 27} Thermal
43
44 stability studies of F₄TCNQ in rr-P3HT,²⁵ s-P3MEET²⁵ and p(g₄2T-T)²⁴ have been reported, with
45
46 F₄TCNQ-doped rr-P3HT exhibiting significantly poorer thermal stability than the other two
47
48 systems. Based on the lower electrical conductivity of F₄TCNQ-doped rr-P3HT films relative to
49
50 F₄TCNQ-doped s-P3MEET and p(g₄2T-T) films after thermal treatment, this instability has been
51
52
53
54
55
56
57
58
59
60

1
2
3 proposed to result from differences in F₄TCNQ dopant sublimation from the three matrices.²⁴⁻²⁵
4
5 However, no direct probe of F₄TCNQ presence was utilized in this prior work.
6
7

8 The starting hypothesis for the work reported here is that the chemical stability of the
9
10 dopant, existing primarily as a radical anion,²⁰ plays a critical role in the thermally-induced
11
12 degradation phenomena observed in F₄TCNQ-doped rr-P3HT films at moderate temperatures.
13
14 Thus, this work was undertaken with the goal of defining with greater chemical specificity the
15
16 thermal instability of F₄TCNQ within doped rr-P3HT films at moderate temperatures (<120 °C)
17
18 and correlating this behavior with the overall electrical conductivity of the film.
19
20

21 Figure 1 summarizes the changes in optoelectronic properties and corresponding
22
23 conductivity measured on co-processed thin (~15 nm) films of this system, as well as elemental
24
25 quantification of possible F₄TCNQ loss using x-ray photoelectron spectroscopy (XPS). Briefly,
26
27 UV-vis spectroscopy and conductivity measurements were performed on P3HT films with
28
29 F₄TCNQ dopant mole fraction (χ_{F_4TCNQ}) of 0.096 (defined by solution composition of F₄TCNQ
30
31 and thiophene equivalents prior to spin-casting) as they were progressively heated in a glove box
32
33 from room temperature to 60, 80, 100, and 120 °C, being held at each temperature for 5 min.
34
35 Immediately after film casting, the UV-Vis spectrum (Figure 1a) clearly indicates a doped largely
36
37 crystalline rr-P3HT film (black) by the presence of the strong $\pi - \pi^*$ P3HT band at ~2.5 eV and a
38
39 broad polaron band from 1.8 to 1.4 eV. The ICT F₄TCNQ^{•-} spectral signatures are still distinct at
40
41 ~1.6 and ~1.4 eV, with a shoulder just below 3.0 eV.²⁴⁻²⁵ As the sample is progressively heated,
42
43 loss of the F₄TCNQ^{•-} absorption signatures is observed, with a fraction of the P3HT polaronic
44
45 absorbance remaining even at 120°C. Two contributions to this loss can be postulated: loss of
46
47 F₄TCNQ^{•-}, possibly with reformation of neutral F₄TCNQ, or changes in P3HT microstructure
48
49 leading to reorientation of F₄TCNQ^{•-}. For randomly oriented P3HT films, changes in orientation

of F₄TCNQ⁻ may make minor contributions to the decrease in intensity of the 1.4 eV UV-vis band.²⁸ However, given that our UV-vis spectroscopy utilized an unpolarized source, these contributions are expected to be minimal to insignificant. Loss of F₄TCNQ⁻ is much more likely. However, there is no evidence for conversion to neutral F₄TCNQ, which would result in a new band at 3.2 eV.²⁴

Figure 1. (a) UV-Vis absorption spectra from a 15 nm-thick film of 0.096 χ_{F_4TCNQ} doped rr-P3HT progressively heated in a glove box for 5 min each at 60, 80, 100 and 120°C. (b) Conductivity from 3 to 5 devices (left axis) and change in normalized F₄TCNQ⁻ absorption at 1.4 eV (right axis) with annealing temperature. (c) Relative atom ratios for N/(N+F), F/(F+C), and N/(N+C) before (solid) and after (hashed) heating. (d) N 1s XPS spectra from 0.096 χ_{F_4TCNQ} film at room temperature (top) and after (bottom) progressive sequence of heating described in (a).

1
2
3 Loss of the 1.4 eV band from F₄TCNQ^{•-} is quantified in Figure 1b (right axis), which
4 rationalizes, at least in part, the loss in conductivity also shown in Figure 1b.¹⁷ In Figure 1b, the
5 conductivity for the same progressive heating sequence decreases from 2.8 x 10⁻¹ to ~1.8 x 10⁻² S
6 cm⁻¹. Temperature-dependent decreases in conductivity of F₄TCNQ-doped P3HT have been
7 reported previously and attributed to sublimation of F₄TCNQ.^{16, 24-27, 29} However, the conductivity
8 of an undoped rr-P3HT film with an analogous heat treatment is ~10⁵ times lower (5 x 10⁻⁷ S cm⁻¹)
9 than that of the thermally annealed doped P3HT film, indicating retention of at least some of the
10 doped film in a conductive state after heating. If it is assumed that the conductivity loss of the
11 doped film is due only to a loss of dopant, with minimal change to charge mobility, then one can
12 use the previously reported conductivity increment per unit dopant to estimate the fractional dopant
13 loss represented by the observed conductivity decrease. Specifically, Duong et al. reported a
14 conductivity increase of 13.3 S cm⁻¹ per unit mole fraction F₄TCNQ dopant added for χ_{F_4TCNQ}
15 between 0.031 and 0.17.¹⁷ Using this value, the decrease in conductivity observed here would
16 suggest an equivalent loss of 20-45% in dopant mole fraction after heating if dopant loss were the
17 mechanism responsible for the conductivity decrease. This large of a F₄TCNQ dopant loss would
18 be readily observable by XPS if loss occurred.

40 Figure 1c shows XPS results in terms of relative atom ratios for different elements before
41 and after heat treatment. These results indicate no statistically significant change after heating for
42 N/(N+F) (both elements unique to F₄TCNQ) in the near-surface region of these films, consistent
43 with minimal thermal decomposition or thermally-driven loss of dopant. Similarly, the relative
44 atom ratios F/(F+C) and N/(N+C) are all within the standard deviations of multiple independent
45 experiments on films before and after thermal annealing indicating conclusively that, for this
46 thermal treatment, F₄TCNQ does not sublime as has been previously reported.^{16, 24-27, 29} We note

that the $F/(F + C)$ ratio for this film is slightly larger than the expected value of 0.015 in the pristine film before heating, but then becomes equal to the expected value after heating. This suggests slight segregation of F₄TCNQ to the upper portions of the pristine doped film before heating with homogenization of the film induced by heating while losing none of the F₄TCNQ to sublimation.

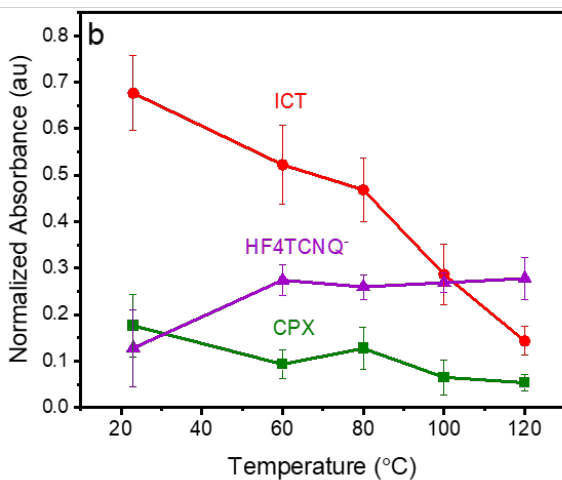

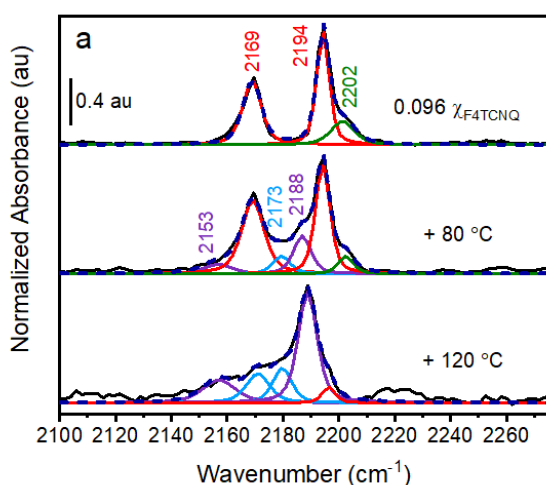

Figure 2. (a) FTIR spectral fits at three temperature points during the progressive heating of a 15 nm-thick film of 0.096 χ_{F_4TCNQ} in rr-P3HT. The red fit line corresponds to the ICT state of F₄TCNQ, the green line to the CPX state of F₄TCNQ, and the purple line to HF₄TCNQ⁻. Cyan peaks were added for a better fit but are currently unidentified. (b) Changes in ICT (2194 cm⁻¹, red), CPX (2202 cm⁻¹, green), and HF₄TCNQ⁻ (2188 cm⁻¹, purple) absorbance values normalized to the $\nu(\text{CH}_2)_{ip}$ at 2852 cm⁻¹ for progressively heated 0.096 χ_{F_4TCNQ} films.

Thermal annealing does elicit spectral changes in the N 1s core level spectra (Figure 1d) in terms of the binding energies and relative intensities of peaks observed. However, definitive assignment of these peaks requires a better understanding of the molecular level changes induced in the films by the thermal annealing process. Thus, FTIR spectroscopy was used to provide additional chemical insight.

FTIR spectroscopy can aid in clarifying the specific molecular nature of dopant forms in the film, as frequency shifts of the $\nu(\text{C}\equiv\text{N})$ mode are highly sensitive to the chemical state of the F₄TCNQ, including the degree of charge transfer between F₄TCNQ and the P3HT.^{19, 23, 30-33} The FTIR spectra in Figure 2a

(unnormalized spectra in Figure S1) show little evidence for CPX in the films after final heating. A low absorbance broad band at higher frequency may indicate a small contribution from neutral F₄TCNQ. However, most notable after heating is the appearance of two new bands in the $\nu(\text{C}\equiv\text{N})$ region at 2188 and 2153 cm⁻¹ at frequencies between known bands of the ICT state (F₄TCNQ^{•-}, $\nu = 2194$ cm⁻¹) and the dianion (F₄TCNQ²⁻, $\nu = 2164$ cm⁻¹).^{31, 34-35} These two bands increase in intensity with annealing temperature, dominating the IR spectrum in films heated to 120 °C (Figure 2a). Exposure to long-wavelength UV light has no impact on this chemistry as reflected in the FTIR spectra (see Figure S2). Significantly, retention of the overall $\nu(\text{C}\equiv\text{N})$ envelope amplitude with heating for all dopant concentrations (see Figure S1) further corroborates the assertion that a significant amount of F₄TCNQ does not sublime.

The correlation between frequency and F₄TCNQ charge state allows assignment of the two new bands in the $\nu(\text{C}\equiv\text{N})$ region that appear with heating. The frequencies of these bands suggest F₄TCNQ species with electron density between that of the anion (ICT) and the dianion. Le et al. investigated the basicity of the reduced states of F₄TCNQ in acetonitrile solutions containing trifluoroacetic acid (TFA) via electrochemistry and UV-vis spectroelectrochemistry,³⁶⁻³⁷ wherein they demonstrated a strong propensity for rapid proton transfer from TFA to F₄TCNQ²⁻ to yield HF₄TCNQ⁻ ($K_{\text{eq}} = 3 \times 10^3$; $k_{\text{f}} = 1 \times 10^{10} \text{ M}^{-1} \text{ s}^{-1}$).³⁶ Further, they noted that HF₄TCNQ⁻ has a low molar absorptivity in the UV-vis region resulting in loss of the dianion band without growth of any new electronic bands. In contrast, in similar FTIR spectroelectrochemical experiments on F₄TCNQ in acetonitrile solutions containing acids recently reported from this laboratory,³⁸ new bands in the $\nu(\text{C}\equiv\text{N})$ region of the FTIR spectra at 2183 and 2153 cm⁻¹ were observed that match in frequency the two new bands observed in the heated F₄TCNQ-doped rr-P3HT films studied here. In the solution FTIR spectroelectrochemistry study, the 2183 and 2153 cm⁻¹ bands were

1
2
3 assigned to the $\nu(\text{C}-\text{C}\equiv\text{N})$ symmetric stretching modes from HF_4TCNQ^- for the unprotonated and
4 protonated sides, respectively (as confirmed by spectral simulations, see Figure S3), that forms by
5
6 a concerted proton-coupled electron transfer.³⁸
7
8
9

10 Further evidence for the presence of HF_4TCNQ^- in the heated films studied here comes
11 from examination of the $\nu(\text{C}=\text{C})$ region of the FTIR spectrum between 1450 and 1600 cm^{-1} (Figure
12 S4). New bands at 1485, 1505, and 1630 cm^{-1} correspond to similar solution-state bands from
13 HF_4TCNQ^- observed in our previous study.³⁸ Thus, we confidently conclude that loss of the ICT
14 state with heating, previously attributed to F_4TCNQ sublimation, is instead due to the formation
15 of HF_4TCNQ^- within these films. This explanation rationalizes loss of the ICT UV-vis signal but
16 with retention of a significant conductivity relative to undoped rr-P3HT after heating. HF_4TCNQ^-
17 is clearly non-chromophoric in the UV-vis region and serves as a weaker dopant of P3HT than
18 F_4TCNQ^- .

26
27
28
29
30

31 Now that the various molecular forms of the F_4TCNQ dopant in these films are identified,
32 we can return to the N 1s XPS data of Figure 1d. Prior to heating, three N 1s peaks are observed
33 in the pristine film. These have been commonly assigned to the ICT species (binding energy 398.2
34 eV), the neutral F_4TCNQ state (400.0 eV),³⁹⁻⁴¹ and a shake-up peak associated with the ICT species
35 (401.8 eV). Similar peaks at 398.6 and 400.2 eV were reported for TCNQ^- ,⁴⁰⁻⁴¹ and similar fits
36 including a shake-up peak have also been reported for F_4TCNQ .⁴¹⁻⁴² With thermal annealing, a
37 significant loss of the 398.2 and 401.8 eV peaks is observed with concomitant loss of the ICT
38 bands in the UV-vis spectrum (Figures 1a) and the ICT $\nu(\text{C}\equiv\text{N})$ band in the FTIR spectrum, thus
39 confirming the assignment of these peaks to the ICT state of F_4TCNQ . Interestingly, however, the
40 N 1s peak at 400.0 eV is retained to a much greater extent after heating and is therefore assigned
41 to HF_4TCNQ^- . This peak must either have a coincidental overlap in binding energy with that of
42
43
44
45
46
47
48
49

60

1
2
3 neutral F₄TCNQ or some small amount of HF₄TCNQ⁻ must be in the films examined by XPS
4
5 before heating, possibly as the result of handling and transport to the surface analysis laboratory.
6
7 DFT calculations of the charge distribution on F₄TCNQ and HF₄TCNQ⁻ (see Figure S5)
8
9 corroborate the coincidental overlap in binding energy by the similarity of the calculated Mulliken
10
11 charges of the nitrogen in F₄TCNQ (-0.51) and the nitrogen on the protonated side of HF₄TCNQ
12
13 (-0.48). The absence of a shake-up peak for HF₄TCNQ⁻ is unremarkable, since the intensity of a
14
15 shake-up process is related to the square of the overlap integral between the valence electron wave
16
17 functions of the initial and final states of the system.⁴⁰ The electronic structure of HF₄TCNQ⁻ is
18
19 expected to be substantially different from that of F₄TCNQ or F₄TCNQ^{•-}, consistent with its non-
20
21 existent absorption in the UV-vis spectrum. Thus, in total, the UV-Vis, FTIR and XPS spectral
22
23 data collectively indicate a growth of HF₄TCNQ⁻ at the expense of F₄TCNQ^{•-} upon thermal
24
25 annealing. We note that this formation of HF₄TCNQ⁻ in turn introduces a slight change in polymer
26
27 microstructure, as indicated by the in- and out-of-plane grazing incidence wide angle x-ray
28
29 scattering measurements in Figure S6, although the edge-on orientation of the structure is retained
30
31 (Figure S7).

32
33
34
35
36
37 We next focus on the possible mechanisms for HF₄TCNQ⁻ formation in the solid state. In
38
39 solution, HF₄TCNQ⁻ can be formed even in the presence of weak proton donors.³⁸ We hypothesize
40
41 that rr-P3HT, more specifically a hydrogen on the alpha-carbon of the hexyl chains, serves as the
42
43 hydrogen source based on the well-known reactivity of this site and the fact that these heating
44
45 experiments were conducted under inert conditions.^{22, 43-44} Two possible mechanisms are proposed
46
47 for formation of HF₄TCNQ⁻ in Scheme 1. The first mechanism involves hydrogen abstraction by
48
49 F₄TCNQ^{•-} from the aliphatic carbon atom alpha to the 3-position of the quinoidal thiophene ring
50
51 to form HF₄TCNQ⁻, followed by rapid recombination of the radicals on the rr-P3HT backbone
52
53
54
55
56
57
58
59
60

Scheme 1. Proposed mechanisms for formation of HF_4TCNQ^- in F_4TCNQ -doped rr-P3HT films with thermal annealing.

through electron rearrangement. This mechanism is essentially identical to that proposed by Northrup for degradation of P3HT,⁴⁵ with the abstracted hydrogen in this case, undergoing a radical combination with $\text{F}_4\text{TCNQ}^{\bullet-}$. The second proposed mechanism involves first a reduction of F_4TCNQ^- by the polaron $\text{P3HT}^{\bullet+}$ to form $\text{F}_4\text{TCNQ}^{2\bullet-}$ and the bipolaron state of P3HT (P3HT^{2+}). The aliphatic carbon alpha to the 3-position of the bipolaron thiophene ring then engages in a rapid or coupled proton transfer to $\text{F}_4\text{TCNQ}^{2\bullet-}$ followed by subsequent electronic rearrangement of the P3HT. Both mechanisms lead to formation of HF_4TCNQ^- and $[\text{P3HT-H}]^+$ and both are plausible given the known reaction chemistry of these and other organic materials.^{44, 46-47} However, two pieces of evidence in combination suggest mechanism 1 is more likely. The first piece of evidence is the absence of a bipolaron P3HT absorption band in the UV-vis spectra at energies <1.2 eV, although admittedly, the small oscillator strength of this bipolaron band⁴⁸ renders this piece of evidence insufficient by itself. The second piece of evidence that argues against mechanism 2 is the absence of any signatures in the $\nu(\text{C}\equiv\text{N})$ region of the FTIR spectra for $\text{F}_4\text{TCNQ}^{2\bullet-}$, which has

Figure 3. (a) Spectrally decomposed FTIR spectra at three temperatures during progressive heating of a 15 nm-thick film of 0.096 χ_{F_4TCNQ} -doped p(g₄2T-T). Fit peaks in red correspond to the ICT state, fit peaks in blue correspond to the dianion state. Inset depicts the p(g₄2T-T) structure.

two relatively intense vibrational modes at distinct frequencies in this region.³⁸ In combination, these two pieces of evidence suggest that the mechanism 1 is more likely.

As a further test of these mechanisms, F₄TCNQ-doped films of the polymer p(g₄2T-T)²⁴ were examined under identical thermal annealing conditions. Instead of hexyl side chains, this polymer possesses tetraethylene glycol side chains, and thus, does not have methylene groups at the alpha position on the 3-position of the thiophene rings (see inset structure in Figure 3). If either of the above mechanisms for HF₄TCNQ⁻ formation with P3HT is correct, no formation of HF₄TCNQ⁻ would be expected with p(g₄2T-T). FTIR results from thermal annealing studies of F₄TCNQ-doped p(g₄2T-T) are shown in Figure 3. We observe only a change in the ratio of the dianion state (blue peaks) co-present with the ICT state in the film (red peaks); no growth of the HF₄TNCQ⁻ bands at 2188 and 2154 cm⁻¹ are observed. These results are in agreement with recent literature that has demonstrated greater functional stability of F₄TCNQ-doped p(g₄2T-T) films upon heating relative to doped rr-P3HT.²⁴ This greater functional stability of F₄TCNQ-doped p(g₄2T-T) is similar to that of F₄TCNQ-doped s-P3MEET, both of which are missing aliphatic methylene carbon atoms alpha to the 3-position of the thiophene rings.²⁵ Thus, this stabilization is the result of mitigation of the reaction chemistry as opposed to the prevention of F₄TCNQ dopant sublimation.

1
2
3 Through this work, we have shown conclusively that the instability of F₄TCNQ doped rr-
4 P3HT films at temperatures between 60 and 120 °C is due to thermally-activated reaction
5 chemistry at the aliphatic carbon atoms alpha to the 3-position of thiophene rings to form
6 HF₄TCNQ⁻, a non-chromophoric weak dopant, resulting in significant degradation of the
7 functional properties of these films. Although exposure to light appears to have essentially no
8 effect on this chemistry (see Figure S2), the effect of atmospheric conditions on this chemistry is
9 being systematically explored and will be reported a later date. In total, this work codifies
10 previously observed behaviors of different conjugated thiophene-based organic semiconducting
11 polymers in the framework of a molecular description of relevant reaction chemistry as a
12 rationalization for degradation of functional properties in some systems but not others. These
13 results elucidate an important design guideline for thiophene-based active layer materials that any
14 structural modifications of thiophene rings to enhance other properties such as solubility or
15 processability should not contain any possibly reactive hydrogen atoms alpha to the ring 3-
16 position.

38 ACKNOWLEDGEMENTS

39
40 The authors acknowledge support of this research by the National Science Foundation under award
41 DMR-1608289. K.E.W. acknowledges financial support through an ARCS Foundation
42 Scholarship and an ACS Division of Analytical Chemistry Fellowship sponsored by Eli Lilly and
43 Company. M.M and I.M. acknowledge generous funding from KAUST for financial support. The
44 authors also acknowledge very useful discussions with Professor Richard S. Glass regarding
45 mechanistic aspects of this work. Use of the Stanford Synchrotron Radiation Lightsource, SLAC

10 SUPPLEMENTARY INFORMATION

11
12 The Supporting Information section contains unnormalized FTIR spectra of the $\nu(\text{C}\equiv\text{N})$ region for
13 three F₄TCNQ mole fraction subjected to progressive heating, pictorial representations and
14 assignments of $\nu(\text{C}\equiv\text{N})$ vibrational modes for each F₄TCNQ species, and FTIR spectra of the
15 $\nu(\text{C}=\text{C})$ region for 0.096 $\chi_{\text{F}_4\text{TCNQ}}$ subjected to progressive heating and grazing incidence wide angle
16 x-ray scattering data of a 0.096 $\chi_{\text{F}_4\text{TCNQ}}$ subjected to progressive heating in a nitrogen glove box.
